7 **Abstract**

8 Numerous studies have demonstrated that significant global changes in wave and storm surge
9 conditions have occurred over recent decades and are expected to continue out to at least 2100.
10 This raises the question as to whether the observed and projected changes in waves and storm
11 surges, will impact coastlines in the future? Previous global-scale analyses of these issues have
12 been inconclusive. This study investigates the south-east coast of Australia over a period of 26
13 years (1988-2013). Over this period, this area has experienced some of the largest changes in wave
14 climate of any coastal region, globally. The analysis uses high-resolution hindcast data of waves
15 and storm surge, together with satellite observations of shoreline change. All datasets have been
16 previously extensively validated against in situ measurements. The data are analysed to determine
17 trends in each of these quantities over this period. The coastline is partitioned into regions and
18 spatial consistency between trends in each of the quantities investigated. The results show that
19 beaches along this region appear to have responded to the increases in wave energy flux and
20 changes in wave direction. This has enhanced non-equilibrium longshore drift. Long sections of
21 the coastline show small but measurable recession before sediment transported along the coast is
22 intercepted by prominent headlands. The recession is largest where there are strong trends of
23 increasing wave energy flux and/or changes in wave direction, with recession rates of up to
24 1m/year. Although a regional study, this finding has global implications for shoreline stability in
25 a changing climate.

26 **1. Introduction**

27 Sandy coastlines are dynamic systems, responding to changes in waves, storm surge, sea level,
28 available coastal sediment supply and human activities (e.g. coastal structures, beach nourishment)
29 (Komar, 1998; Masselink, et al., 2016). These changes occur on a variety of spatial and temporal
30 scales. Spatially, changes in beach alignment and the presence of coastal shoreline features
31 (headlands and bays) impact both the wave climate for individual beaches and the characteristics
32 of longshore drift. At temporal scales of days, beach erosion results from individual storms
33 (Komar, 1998; Harley, et al., 2017; Masselink, et al., 2016). At time scales of 2 to 10 years,
34 changes in storminess associated with climate indices (e.g. El Niño) (Ranasinghe, et al., 2004;
35 Harley, et al., 2011; Barnard, et al., 2015; Vos, et al., 2023) can result in sustained impacts on
36 beach systems. Longer term changes in mean sea level as a result of climate change are also
37 predicted to result in coastal recession (Hinkel, et al., 2013; Ranasinghe, 2016; Vousedoukas, et al.,
38 2020; Ranasinghe, et al., 2021; Vitousek, et al., 2023). It should be noted that throughout this paper

39 we refer to shorter-term changes in beach location due to storms or a series of storms as erosion
40 or accretion. Longer-term changes such as those due to climate change are referred to as recession
41 or progradation.

42 Waves and storm surges are generated by environmental variables (wind and sea level pressure
43 gradient). It has been shown that these environmental variables are impacted by climate change
44 and hence long-term historical changes (trends) in waves (Wang & Swail, 2001; Wang, et al.,
45 2009; Hemer, 2010; Young, et al., 2011; Aydoğan & Ayat, 2018; Zheng & Li, 2017; Young &
46 Ribal, 2019; Takbash & Young, 2020; Reguero, et al., 2019; Cao, et al., 2021; Young & Ribal,
47 2022; Liu, et al., 2022; Morim, et al., 2022; Erikson, et al., 2022) and storm surges (Paprotny,
48 2014; Androulidakis, et al., 2015; Cid, et al., 2016; Muis, et al., 2016; Kim, et al., 2017; Feng, et
49 al., 2018; Ghanavati, et al., 2023) have been observed. A number of studies have also projected
50 continued global increases (positive trends) in wave height over the 21st century, particularly in
51 the Southern Hemisphere, under plausible climate change scenarios (Hemer, et al., 2013; Meucci,
52 et al., 2020; Hochet, et al., 2021; Liu, et al., 2022; Meucci, et al., 2023; Morim, et al., 2023; Liu,
53 et al., 2023).

54 If sandy coasts are impacted by changes in wave and storm surge conditions, the potential for
55 continued increases in the values of these variables in the future raises the question as to what
56 impact this may have on sandy coastlines and associated communities. As a means of determining
57 potential future impacts, the obvious precursor is to assess the impacts that historical changes in
58 long-term wave and storm surge conditions have had on coastlines. In the first study of its type,
59 Ghanavati, et al. (2023) investigated this issue at global scale by using long-term modelled wave
60 and storm surge data together with satellite observations of beach recession/progradation over the
61 last 30 years. They found that, noting the relatively small trends in wave and storm surge conditions
62 over this period, the accuracy of the available data, and other unrelated impacts on shoreline
63 response (e.g. availability of sediment, human impacts), no clear relationship was evident.

64 In order to address the limitation of the Ghanavati, et al (2023) work, the present study examines,
65 in much finer detail, the south-east coastline of Australia. This is an area where long-term trends
66 in wave conditions are some of the largest in the world, responding to changes in wave climate in
67 the Southern Ocean (Liu, et al., 2022). Therefore, if there is a causal link between changes in long-
68 term wave and storm surge climate and shoreline response, one would expect clear signs in this
69 region. As a regional area is considered, it is possible to use higher resolution data (both model
70 and satellite) removing uncertainties in the global-scale Ghanavati, et al (2023) study. In addition,
71 the regional-scale study enables an analysis of the role beach compartments play in defining
72 sediment transport. As such, one can investigate changes in longshore drift due to changes in wave
73 climate and the characteristic signature of such non-equilibrium transport with eroding beaches
74 and deposition of sediment behind peninsulas.

75 Although the present study is regional, the area being studied is a proxy for the potential impacts
76 one may see in other regions of the world as changes in wave and storm surge climate are projected

77 to continue to change in the future. Hence, the findings of the study have global implications for
78 shoreline response in the future. The study is unique in that it has been possible to combine high
79 resolution datasets for waves, storm surge and shoreline response and addresses a previously
80 unexplored area of shoreline response in a changing climate.

81 The structure of the paper is as follows. Section 2 outlines the study area, data sets and analysis
82 techniques used in the study. Results are given in Section 3, including the observed relationships
83 between changes in wave and storm surge quantities and beach recession/progradation. Discussion
84 and conclusions are provided in Section 4.

85

86 **2. Methodology**

87

88 **2.1 Study Area**

89 The study region is shown in Figures 1 and 2, and covers an area of 137E°–155°E, 35S°–45°S.
90 Three Australian coastal states span this domain, Victoria, southern New South Wales and the
91 island of Tasmania in the south of the domain. The south-eastern coast of the mainland of Australia
92 (Victoria), the coastal area of the study, is separated from Tasmania by the relatively shallow Bass
93 Strait. The area is exposed to a particularly complex wave climate (Liu, et al., 2022). To the west,
94 the coast is exposed to the Southern Ocean and hence experiences a very energetic wave climate
95 with recorded significant wave height as high as 10m (Meucci, et al., 2023). The wave climate of
96 this region is dominated by south-westerly Southern Ocean swell. Central regions of the study
97 domain are protected by the island of Tasmania and have a mixed wave climate with swell from
98 both the south-west and south-east and locally generated wind sea. To the east, the wave climate
99 is more heavily dependent on the local wind-sea but with south-easterly swell still playing a role
100 (Liu, et al., 2022).

101

102 Both observational data from satellite altimeters (Young, et al., 2011; Young & Ribal, 2019;
103 Timmermans, et al., 2020) and model hindcasts (and reanalyses) (Cao, et al., 2021; Young & Ribal,
104 2022) show that over the last 35 years, there has been a small global increase in mean significant
105 wave height. This increase is largest in the Southern Ocean (approximately 3mm/year or an
106 increase of 3% over the last 30 years), which results in impacts across the Indian, South Pacific
107 and South Atlantic Oceans due to radiating swell. Therefore, the study area is a location where
108 relatively large changes in significant wave height have occurred over the period.

109

110 **2.2 Datasets**

111 This study uses regional datasets for each of wave, storm surge, and coastal change from which
112 the historical trend magnitudes of the various quantities were calculated. The datasets under
113 consideration cover different periods of time, and thus, to ensure consistency across analyses, a

114 common time period from 1988 to 2013 was selected. A description of each dataset used in the
115 study is provided below.

116

117 Liu et al. (2022) regional wave hindcast is a high-resolution regional wave hindcast dataset based
118 on a WAVEWATCH III model with an ST6 physics package (Liu, et al., 2021). The regional
119 model covers the domain shown in Figure 2 using an unstructured grid with a coastal resolution
120 as small as 500m and a coarser deep water resolution as large as 10km. The regional model is
121 nested within a global model using the same ST6 physics (Liu, et al., 2021). Both the regional and
122 global models are forced with ERA5 winds (Hersbach, et al., 2020). The regional wave model
123 dataset has been extensively validated (Liu, et al., 2022; Liu, et al., 2023) against both a network
124 of coastal buoys and satellite altimeter data. Wave data were available from the hindcast with a
125 temporal resolution of 1 hour. The period of the hindcast was from 1981 to 2020. The dataset's
126 high resolution is particularly important for studying coastal regions, where wave conditions can
127 vary significantly over short distances. Additionally, the long period of coverage allows us to
128 identify and analyze trends in the wave climate over several decades, providing insight into the
129 possible effects of historical climate change on the region.

130

131 Colberg, et al. (2018) Australian water level hindcast is a dataset of sea level simulations for the
132 Australian coastline. The dataset was generated using the Regional Ocean Modelling System
133 (ROMS) (Shchepetkin & McWilliams, 2005), which was run in a depth-integrated form on a 5 km
134 resolution grid for the Australian region. Tidal currents and heights at open boundaries were
135 specified from the TPXO7.2 global model (Egbert & Erofeeva, 2002). TPXO7.2 best fits (in a
136 least squares sense) the Laplace tidal equations and along track averaged data from
137 TOPEX/Poseidon and Jason altimetry data. The ROMS model was run for the period 1981-2013
138 and was forced with NCEP Climate Forecast System Reanalysis (CFSR) (Saha, et al., 2010) wind
139 and surface pressure data. The model has been validated at 14 tide gauge locations around the
140 Australian coastline (Colberg, et al., 2018). Again, the output was available on an hourly basis.

141 Bishop-Taylor et al., (2021) Geoscience Australia beach dataset is a high-resolution regional
142 dataset of shoreline change rate for the coast of Australia. The dataset utilizes a combination of
143 satellite visual data and tidal modelling to map shoreline change, with an along-coast resolution of
144 30m for non-rocky (sandy or muddy) areas. The dataset provides annual values of the shoreline
145 position over the period 1988 to 2019. The dataset has been extensively validated using in-situ
146 measurements, comprising 330 validation transects, each spanning over 10 years of coastal
147 monitoring data. The Mean Absolute Error (MAE) in the trend across these validation points was
148 0.35 m/year (Bishop-Taylor, et al., 2021).

149 **2.3 Trend calculation**

150 Each of the datasets (waves, storm surge, shoreline location) are defined at different resolution and
151 in different manners (structured and unstructured grids, specific shoreline positions), therefore
152 none of these quantities are co-located. As shown by Ghanavati, et al., (2023) and subsequently

153 confirmed in Figures 3, 4 and 5, trends in both wave height and storm surge quantities generally
154 vary smoothly along extended coastal regions (100s of kilometres). Shoreline
155 recession/progradation rate can, however, vary rapidly in magnitude and sign over relatively short
156 spatial scales (10s of kilometres) (Luijendijk, et al., 2018; Ghanavati, et al., 2023). That is, one
157 beach can be receding whilst the next is prograding. As such, simple scatter plots of rates of change
158 of wave and storm surge quantities verses recession/pogradation rates are not meaningful. Rather,
159 one needs to consider relationships over spatial regions of the coastline. To achieve such an
160 analysis, we divide the study domain in Figure 1 into six regions, each spanning 2° in longitude –
161 (a) 138°E - 140°E , (b) 140°E - 142°E , (c) 142°E - 144°E , (d) 144°E - 146°E , (e) 146°E - 148°E and (f)
162 148°E - 150°E from west to east. These regions span the differing wave climates of the study
163 domain (see Figure 2 and subsequent discussion). For analysis purposes, we present data as
164 follows. Wave quantities are presented both as colour shaded plots, and at shoreline locations
165 corresponding to ocean points defined by the unstructured WAVEWATCH III computational grid.
166 Storm surge quantities are shown at the locations corresponding to the ocean points nearest the
167 land/sea transition of the ROMS 5km computational grid. Coastal change points are as defined at
168 coastal locations in the Bishop-Taylor et al., (2021) dataset, which has an along-cost resolution of
169 30m.

170 Each of the three datasets used in the study covers a different period of time: wave hindcast - 1981
171 to 2020, storm surge data - 1981 to 2013, and shoreline change data - 1988 to 2019. To ensure a
172 consistent evaluation of the trends and variability in the oceanic parameters, a common analysis
173 period of 1988 to 2013 was selected for the study.

174 For each of the datasets, a range of quantities to be investigated were calculated. These include:
175 waves – mean significant wave height (H_s), 95th percentile significant wave height (H_s^{95}), mean
176 wave energy flux ($C_g E$), mean wave period (T_m) and mean wave direction (θ_m), where C_g is the
177 group velocity of waves and $E = H_s^2 / 16$ is the wave energy. The hourly data from the regional
178 wave model was used to calculate annual values of each of these quantities.

179 As noted above, various datasets have different temporal and spatial resolutions and hence slightly
180 different approaches were used to evaluate the variability and extremes of oceanic parameters. The
181 wave and surge time series were collected at a temporal resolution of 1 hour, while the shoreline
182 dataset provided annual shoreline change with reference to the shoreline location in 2019.
183 Therefore, annual mean values of wave parameters including significant wave height, wave energy
184 flux, wave direction and wave period were calculated. Furthermore, the extremes were determined
185 by calculating annual higher percentiles (95th, 98th, and 99th) for significant wave height and
186 surge level. These metrics provide a consistent basis for evaluating the variability and extremes of
187 the oceanic parameters across different datasets. As the various percentile thresholds gave similar
188 results, extreme events were determined as occasions on which the time series exceeded the 95th
189 percentile but with such events separated by a minimum of 48 hours. The number of such events

190 in each year were defined as $N_{H_s^{95}}$. In a similar fashion, storm surges were defined as occasions
 191 when the water surface elevation, η , exceeded the 95th percentile (η^{95}) and the number of such
 192 events was defined as $N_{\eta^{95}}$. Again, annual values of these quantities were determined. The annual
 193 values of shoreline position from the Bishop-Taylor et al. (2021) data were defined in a similar
 194 manner and represented as C_{GA} .

195 The annual values of each quantity were then used to determine linear trends over the period 1988-
 196 2013. Both linear regression and the non-parametric Tiel-Sen estimator (Sen, 1968) were used for
 197 this purpose. As the resulting values were very similar, the Sen slope estimates are used in the
 198 subsequent analysis. The resulting trend values are represented as: ΔH_s , ΔH_s^{95} , $\Delta C_g E$, $\Delta \theta_m$,
 199 $\Delta N_{H_s^{95}}$; $\Delta \eta^{95}$, $\Delta N_{\eta^{95}}$; ΔC_{GA} .

200

201 3. Results

202 3.1 Wave climate

203 Figure 2 shows the mean wave climate of the study area and how it has changed over the period
 204 1988 to 2013 as indicated by the Liu, et al. (2022) hindcast. Figures 2a and 2b show the mean
 205 significant wave height \bar{H}_s and wave energy flux, $\overline{C_g E} = \rho g^2 H_s^2 T_m / (64\pi)$, respectively. As
 206 noted above, the significant wave height and wave energy flux vary significantly across the study
 207 area. In the west, the coastline is exposed to energetic Southern Ocean swell with mean H_s of
 208 approximately 3m. In the eastern regions of the study area, where there is protection provided by
 209 the island of Tasmania, mean H_s decreases significantly to less than 1.5m, a decrease by a factor
 210 of approximately 2. The wave energy flux shows an even more significant change, with mean
 211 values varying from approximately 60kW/m in the west to 15kW/m in the east, a factor of 4. The
 212 substantial reduction in wave energy flux is attributed to the protection provided by the island of
 213 Tasmania, which leads to a decrease in both H_s and T_m . As shown by Liu, et al. (2022), the
 214 mean/peak wave direction also changes significantly across the domain. In the west, the dominant
 215 wave direction is defined by energetic south-westerly swell. In the east, the protection provided by
 216 the island of Tasmania means that swell entering the area is predominately from the south-east.

217 The changes in wave climate over the study period are also significant across this region. As noted
 218 above, a range of studies have shown that the Southern Ocean wave climate has increased over the
 219 past 35 years (Young, et al., 2011; Young & Ribal, 2019; Cao, et al., 2021; Young & Ribal, 2022).
 220 Swell from the Southern Ocean dominates the western areas of the study region and hence there
 221 have been significant changes in the wave climate, as shown by Figures 2c-h. In the west, H_s has
 222 increased by approximately 5% (Figure 2c) over the study period and $C_g E$ by approximately 14%
 223 (Figure 2d). In contrast, in the east, where the wave climate is not as exposed to Southern Ocean

224 swell, these values decrease to approximately zero (no change). Figures 2e and f clearly show that
225 the positive trends in H_s are due to changes in both swell and local wind-waves. Figure 2g also
226 shows that there have been only small changes in T_m across the domain.

227 The most dramatic changes in wave climate concern the mean wave direction, θ_m . Over the
228 western regions of the study domain, there has been a small counter-clockwise rotation of the mean
229 wave direction (less than 1.5°). This is a result of the gradual southward movement of Southern
230 Ocean low pressure systems over recent decades (Morim, et al., 2022). This small change in deep
231 water wave direction, significantly impacts the shadow region in the lee of Tasmania and hence
232 the wave direction, resulting in much larger counter-clockwise rotations of approximately 5°
233 (Figure 2h). These values reduce towards the coast of mainland Australia (eastern area of study
234 region) but are still larger than 3° .

235 **3.2 Storm Surge Climate**

236 As noted above, storm surges were defined as events where the water surface elevation exceeded
237 the 95th percentile value, η^{95} . Figure 3 and 4 show plots for each of the sub-regions referenced in
238 Figure 1. These figures show colour contoured values of $\Delta C_g E$ (Figure 3) and $\Delta \theta_m$ (Figure 4),
239 coastal values of $\Delta \eta^{95}$ and ΔC_{GA} . In contrast to the wave climate, changes in storm surge, $\Delta \eta^{95}$
240 are very consistent along the coastline of the study area. Values of $\Delta \eta^{95}$ are negative along the
241 entire coastline, decreasing in magnitude from approximately -0.3cm/year in the west to
242 -0.2cm/year in the east. The fact that the magnitude of storm surges has been decreasing over this
243 period is consistent with the observations of Liu, et al. (2023) that as Southern Ocean low pressure
244 systems move south, they increase the mean atmospheric pressure and reduce the pressure gradient
245 over southern Australia. As surface pressure (and wind) drives storm surge, this results in a
246 tendency for a reduction in the magnitude of storm surges.

247

248 **3.3 Relationship between waves, storm surge and shoreline change**

249 As previously shown at global scale by Luijendijk, et al. (2018) and Ghanavati, et al. (2023),
250 recession/progradation rates vary in magnitude and sign on relatively small spatial scales. This is
251 because sediment transport can be both offshore/onshore as well as longshore. In the case of non-
252 equilibrium longshore transport of sediment, one would expect some beaches to recede whilst
253 other receive sediment from these beaches and hence prograde. Ghanavati, et al. (2023) speculated
254 that coastlines which show such non-equilibrium behaviour may be responding to long-term
255 changes in the environmental forcing provided by trends in waves and storm surge. A causal
256 relationship is, however, complicated by other variables which may have a larger impact on beach
257 position. These additional factors include the availability of sediment supplied to beach
258 compartments from fluvial sources and the impacts of human-induced interventions such as coastal

259 structures and beach nourishment (Ranasinghe, 2016). Ghanavati, et al. (2023) limited
260 recession/progradation data to values in the range $\pm 1\text{m/year}$ to confine the datasets to changes
261 which may be a result of long-term processes rather than fluvial and human-induced influences,
262 which tend to be much larger in magnitude (Luijendijk, et al., 2018).

263 Therefore, following these precedents, in Figures 3 – 6, the quantity ΔC_{GA} has been filtered to retain
264 only values in the range $\pm 1\text{m/year}$. Figure 5 shows values of ΔC_{GA} (in the range $\pm 1\text{m/year}$) as a
265 bar chart along the coastline from 138E° to 150E° . Each of the 2° regions shown in Figures 1, 4
266 and 5 is marked along the longitude axis. As expected, values of ΔC_{GA} in Figures 3, 4 and 5 show
267 both positive (progradation) and negative (recession) values. To quantify recession/progradation,
268 values of ΔC_{GA} in the range -0.05m/year to -1.00m/year are classified as recession, values in the
269 range $+0.05\text{m/year}$ to $+1.00\text{m/year}$ as progradation and values in the range $\pm 0.05\text{m/year}$ as
270 representing stable coastlines. Table 1 shows the percentage of coastal locations classified as
271 receding, prograding or stable under these criteria. In addition, Figure 6 shows histograms of the
272 distribution of the magnitudes of the values of ΔC_{GA} .

273 Table 1 and Figure 6 show that the sections (c) 142E° - 144E° and (f) 148E° - 150E° are
274 predominately receding. Segment (d) 144E° - 146E° shows quite large values of both recession and
275 progradation (see Figure 5) but with more locations prograding than receding. However, this
276 region is complicated by the presence of Port Phillip Bay. The other segments (a), (b) and (e)
277 show no clear difference between the percentage of receding and prograding locations.

278 To understand the results shown in Table 1, we consider each of the two degree sections shown in
279 Figures 3, 4 and 5. In these figures, values of the trend in wave energy flux, $\Delta C_g E$ (Figure 3) or
280 wave direction, $\Delta \theta_m$ (Figure 4) are shown as colour shaded contours over the regions. The trend
281 in storm surge (always negative) are shown as colour coded squares at 5km intervals along the
282 shoreline, at the resolution of the water level model. The satellite-derived values of trend in
283 shoreline location at each beach location (Bishop-Taylor, et al., 2021) are shown as colour coded
284 filled circles, at the 30m along-coast resolution.

285 Figures 3a and 4a show the region from 138E° to 140E° (segment (a), Victor Harbour to Cape
286 Jaffa). This region shows relatively small positive values of $\Delta C_g E$ (approximately 0.01kWm^{-1}
287 $^1/\text{year}$) and a small counter-clockwise rotation of the mean wave direct (approximately
288 -0.02deg/year or 0.6° over 30 years). In response to these small changes in wave properties there
289 is no consistent changes in shoreline. In the western regions (138.6E° - 139.2E°) the shoreline is
290 prograding. However, this may be associated with fluvial sediments, as this region is the ocean
291 entrance of Lake Alexandrina and the mouth of the Murray River. These results are consistent with
292 the bar chart of Figure 5 and the results in Table 1 and Figure 6a that there is no clear difference
293 between recession and progradation for segment (a).

294 Moving east to segment (b), values of $\Delta C_g E$ increase (Figure 3b) and the region shows small
295 receding shorelines (139.6E°- 141.0E°). This changes to progradation between 141.0E°-141.2E°,
296 west of Cape Bridgewater. This behaviour is consistent with sediment being moved along the
297 shoreline west to east from 139.6E°- 141E° by the increasing wave energy flux and the prevailing
298 wave direction from the south-west. This sediment transport is interrupted by Cape Bridgewater
299 resulting in the progradation between 140.8E°-141.2E°. The overall balance between these regions
300 results in no clear difference between locations receding and prograding in Table 1 and Figure 6b.

301 The strong positive trend in wave energy flux is maintained east of Cape Bridgewater (segment
302 (c), Figures 3c) with small counter-clockwise rotation of the mean wave direction (Figure 4c).
303 Along this extended region of the coast to Cape Otway (141.6E°-143.6E°), the coastline shows
304 small recession (approximately -0.1m/year – 3m over the measurement period of 30 years). East
305 of Cape Otway, the magnitude of the recession decreases and the shoreline shows little net change
306 in location. This behaviour is consistent with the reduced impact of south-westerly swell east of
307 Cape Otway, which provides some shelter from such waves. Table 1 and Figure 6c show that
308 summed across the full segment (c), a total of 53% of locations are receding and only 27%
309 prograding.

310 East of Cape Otway, the wave energy flux climate near the coast decreases (Figure 2b), as Cape
311 Otway provides protection from the south-westerly swell and $\Delta C_g E$ also decreases as the
312 protection provided by Tasmania becomes important (Figure 3d). The shoreline trends, ΔC_{GA} , are
313 complicated by the presence of Port Phillip Bay (Figures 3d, 4d). From Cape Otway to Inverloch
314 (143.6E°- 145.8E°) there is relatively little change in ΔC_{GA} . The relatively small region from
315 Inverloch to Wilson's Promontory (145.8E° - 146.4E°) shows a receding shoreline, previously
316 noted in studies of the area (Leach, et al., 2023). As a result, there is no clear overall differences
317 between recession and progradation for this section (Table 1 and Figure 6d). However, if one
318 considers just the ocean beaches (exclude Port Phillip Bay in Figures 3d and 4d), then there is
319 small recession along the entire coastline of section (d).

320 East of Wilson's Promontory the coastline is characterized by very long beaches and barrier islands
321 (Ninety-mile beach). This region from 147E° to 149.6E° (Wilson's Promontory to Cape Howe)
322 (Figures 3e-f, 4e-f) is characterized by a large counter-clockwise rotation of the mean wave
323 direction. The region immediately east of Wilson's Promontory (146.5E – 147E) shows strong
324 progradation. The remainder of this extended coastline, however, shows consistent recession of
325 approximately -0.5m/year (15m over the measurement period), particularly for section (f). This
326 section shows the strongest recession of any extended section, with Table 1 showing 60% of
327 locations receding and only 30% prograding. As noted above, the dominant swell in this region is
328 from the south-east and, although the changes in wave energy flux are small, there has been a
329 significant counter-clockwise rotation of the wave direction over the study period. This results in
330 the wave direction gradually becoming more shore-parallel. Therefore, the shoreline change noted
331 above is consistent with an increase in longshore drift (east to west) with sediment being

332 accumulated to the east of Wilson’s Promontory. We should also note that this area east of Wilson
333 Promontory is one of the few estuarine environments along the entire Victorian coast and hence
334 some of the observed progradation may be due to fluvial deposits and ebb-tide delta formation
335 (Konlechner, et al., 2020).

336 The results above use the percentage of coastal locations prograding or receding as the measure of
337 whether the beach is responding to long term changes in waves and/or storm surge. As such, it
338 does not consider the magnitudes of the progradation or recession. Figure 6 shows histograms of
339 the magnitudes of the progradation/recession rates for each coastal sections. The figure confirms
340 the results above showing sections (c) 142E° – 144E° and (f) 148E° – 150E° are clearly receding
341 with other sections less clear, as explained for each section above.

342 In the above analysis, we speculate that changes in wave energy flux, $\Delta C_g E$ and mean wave
343 direction, $\Delta \theta$ are the primary drivers of the observed changes in shoreline. The observed data
344 supports this speculation. The Supplementary Material shows plots similar to Figures 3 and 4 for
345 changes in the other related quantities: significant wave height, ΔH_s (Figures S1 a-c and S1 d-f),
346 extreme significant wave height, ΔH_s^{95} (Figures S2 a-c and S2 d-f), mean wave period, ΔT_m
347 (Figures S3 a-c and S3 d-f) and number of extreme wave events, $\Delta N_{H_s^{95}}$ (Figures S4 a-c and S4 d-
348 f).

349

350 **4. Discussion, conclusions and future work**

351 Ghanavati, et al. (2023) found that at global scale, they could not distinguish a clear relationship
352 between modelled (and observed) changes in wave energy flux and storm surge over the last 30
353 years and changes in shoreline position. The present dataset considers these relationships at higher
354 resolution for the region of south-east Australia. This region is important in that it is an area with
355 major spatial variations in wave energy flux climate (mean conditions) and some of the largest
356 coastal trends in wave energy flux and mean wave direction globally in the last 30 years. In
357 addition, both high resolution coastal wave and storm surge hindcasts are available, as well as high
358 resolution observations of shoreline changes. As such, this is a unique region to determine if
359 observable changes in shoreline position are evident as a consequence of long term changes in
360 wave (and/or storm surge) climate.

361 The results show clear changes in shoreline position, which are consistent with positive trends in
362 wave energy flux and changes in mean wave direction. In the western regions of the domain the
363 mean wave direction is from the south-west and there have been positive trends in wave energy
364 flux, $\Delta C_g E$ of approximately 14% (6/43kW/m). This appears to have resulted in non-stationary
365 longshore drift from west to east and shoreline changes of approximately 3m over the 30 year
366 study period.

367 In the central regions of the study domain both the mean wave energy flux and trends in wave
368 energy flux decrease, as the island of Tasmania provides protection from the south-westerly swell.
369 In this region there are no consistent trends in shoreline position with a similar number of coastal
370 locations receding and prograding. Although ocean beaches do show small recession.

371 To the eastern end of the study domain, the protection provided by Tasmania and the deepwater
372 counter-clockwise rotation of the mean wave climate means that the wave shadow of Tasmania
373 results in a relatively large counter-clockwise rotation of the mean wave direction (up to 6° over
374 the last 30 years). These changes in mean wave direction appear to be driving non-stationary
375 behaviour of the beach systems in the region with the coastline from 146° to 149° (approximately
376 300 km) receding by up to 30m over the 30 year study period.

377 The results presented in this analysis are consistent with a study of this same region by Konlechner,
378 et al. (2020) using lower resolution shoreline change data (Luijendijk, et al., 2018). The shoreline
379 change “hot-spots” of that study are consistent with the present results. The results of the present
380 study are also consistent with the global findings of Ghanavati, et al. (2023). Here, we find that
381 long term changes in wave climate can apparently drive long-term changes in beach location but
382 that relatively large changes in wave energy flux and/or direction are required to produce
383 measurable changes in beach position. As noted, the study region has both a very energetic wave
384 climate and some of the largest trends in this climate of any coastline. However, even in a region
385 such as this, where long-term changes in wave energy flux are relatively large, the resulting
386 changes in beach location are only approximately 1.0 m/year or 30m over the study period.

387 In the present analysis, we speculate that the observed changes in shoreline position in the western
388 section of the domain are driven by non-stationary longshore drift from west to east with sediment
389 transport being intercepted by Cape Bridgewater. Such behaviour is consistent with the observed
390 increases in wave energy flux and the predominately south-westerly swell. In the eastern sections
391 of the domain, we speculate that there is sediment transport from the east to west, intercepted by
392 Wilson’s Promontory. This speculation is consistent with the predominately south-easterly swell
393 in the region and the observed counter-clockwise change in mean wave direction over the study
394 period.

395 Although such speculation is consistent with the datasets, other processes may also have an impact
396 on shoreline change. The most obvious such change is sea level rise, which could be expected to
397 cause shoreline recession. Observations (Watson, et al., 2015; Nerem, et al., 2018) indicate that in
398 recent years sea level rise in the Australia region has been approximately 3mm/year. The bed slope
399 along the south-eastern coast of Australia is on average approximately 1:100 (Athanasίου, et al.,
400 2019). Therefore, application of Bruun’s rule (Bruun, 1962) would suggest a uniform recession of
401 approximately 0.3 m/year. Such a value is smaller than, but comparable, to the observed recession
402 in the western and eastern portions of the study domain. Recession due to sea level rise, however,
403 would not account for the observed progradation west of Cape Bridgewater or east of Wilson’s
404 Promontory. In addition, Bishop-Taylor, et al. (2021) indicate that over their full dataset for

405 Australia, approximately the same number of beaches are receding (11.1%) as prograding (11.0%).
406 Table 1 indicates that for the present study region this is also the case. Sea level rise would be
407 expected to result in a net recession of beaches. In contrast non-equilibrium longshore drift driven
408 by changes in wave climate will cause some beaches to recede whilst other prograde.

409 Therefore, we conclude that the present results are more consist with the impacts of changes in
410 wave climate rather than sea level rise.

411 Although the present study is regional, it has global implications for the magnitude of changes in
412 shoreline response which may result in other regions of the world under future projections of
413 changes in wave climate. The present study clearly shows that impacts of changing wave climate
414 will have strong regional characteristics and that it is important to consider the unique nature of
415 each region in determining potential impacts. The response to individual coastal compartments
416 will differ in terms of the magnitude of the response and even the sign (recession verses
417 progradation).

418 As noted, the present analysis provides the first evidence of a causal relationship between long-
419 term climate trends in waves and shoreline change. It does, however, have a number of limitations
420 which should be addressed in future research. These future studies could include:

- 421 • Detailed sediment transport modelling to assess whether the observed changes in wave
422 energy flux and wave direction would be expected to result in non-stationary longshore
423 drift of the magnitude observed in the recorded shoreline position.
424
- 425 • The extraction of shoreline position from relatively low-resolution satellite images is
426 computationally challenging. The Bishop-Taylor, et al. (2021) dataset represents a
427 significant advance in resolution and accuracy. Further developments in the use of
428 Artificial Intelligence approaches to determining shoreline postion are expected to further
429 reduce errors in such data.
430
- 431 • The present analysis is limited to south-east Australia, as there were high-resolution
432 datasets of long-term changes in waves, storm-surge and shoreline position available for
433 this region. Dedicated projects modelling specific areas for the purpose of better
434 determining the relationships between changes in these quantities would better quantify the
435 likely impacts of future changes on vulnerable shoreline.

599 Figure 2: Wave climate and trends in the study region of south-eastern Australia over the period
 600 1988 to 2013 as modelled by the Liu, et al. (2022) regional wave model. (a) mean significant
 601 wave height, (b) mean wave energy flux, (c) trend in significant wave height, (d) trend in wave
 602 energy flux, (e) trend in wind-wave portion of the spectrum, (f) trend in swell portion of the
 603 spectrum, (g) trend in mean wave period, (h) trend in mean wave direction.

604

605 Figure 3 a-c: Trends in: wave energy flux, $\Delta C_g E$ shown as colour shaded values over the
 606 domain, storm surge, $\Delta \eta^{95}$ shown as colour shaded squares at coastal model locations and
 607 shoreline progradation/recession, ΔC_{GA} shown as colour shaded circles at beach locations.
 608 Results shown for sections (a) 138E°-140E°, (b) 140E°-142E°, (c) 142E°-144E°.

618 Figure 3 d-f: Trends in: wave energy flux, $\Delta C_g E$ shown as colour shaded values over the
 619 domain, storm surge, $\Delta \eta^{95}$ shown as a colour shaded squares at coastal model locations and
 620 shoreline progradation/recession, ΔC_{GA} shown as colour shaded circles at beach locations.
 621 Results shown for sections (d) 144E°-146E°, (e) 146E°-148E° and (f) 148E°-150E°.

622

629 Figure 4 a-c: Trends in: mean wave direction, $\Delta\theta_m$ shown as colour shaded values over the
 630 domain, storm surge, $\Delta\eta^{95}$ shown as colour shaded squares at coastal model locations and
 631 shoreline progradation/recession, ΔC_{GA} shown as colour shaded circles at beach locations.
 632 Results shown for sections (a) 138E°-140E°, (b) 140E°-142E°, (c) 142E°-144E°.

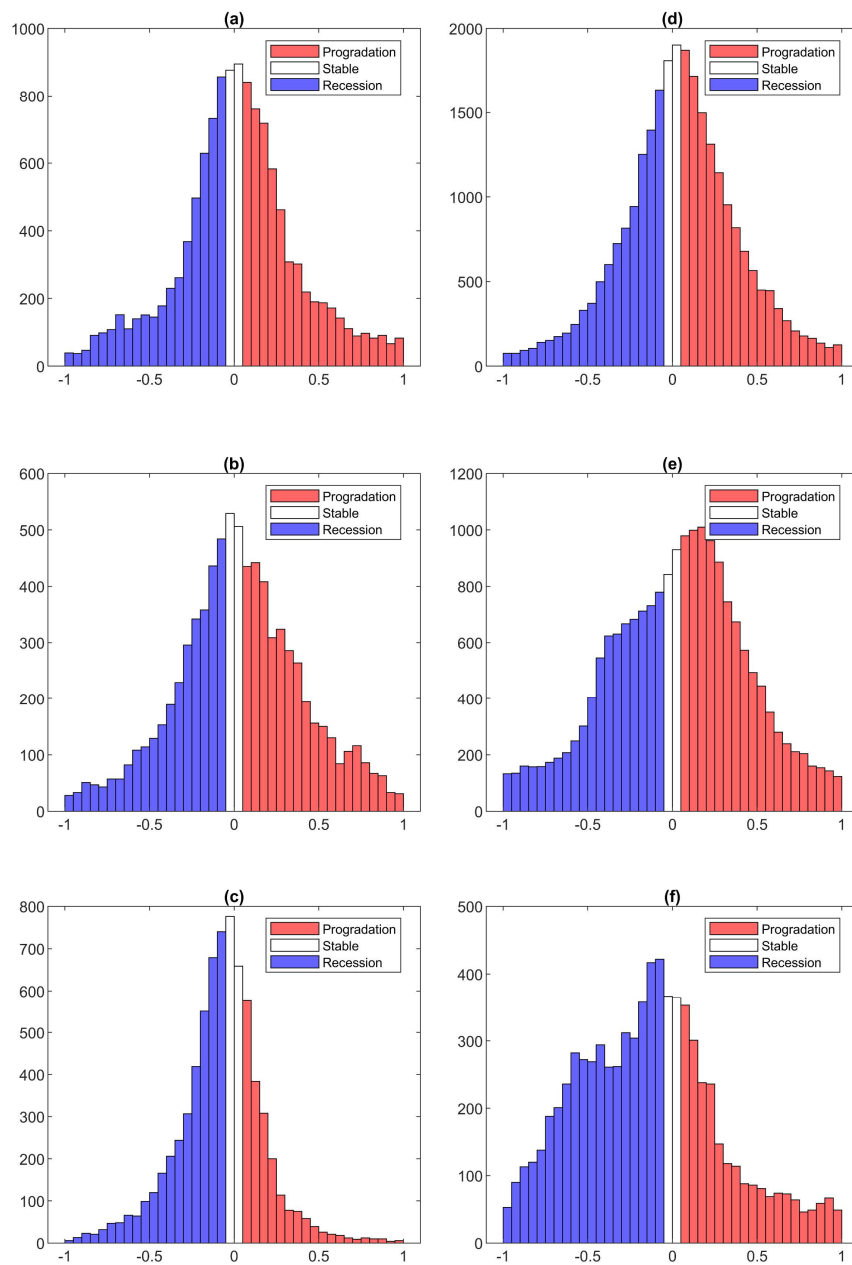

634 Figure 4 d-f: Trends in mean wave direction, $\Delta\theta_m$ shown as colour shaded values over the
 635 domain, storm surge, $\Delta\eta^{95}$ shown as a colour shaded squares at coastal model locations and
 636 shoreline progradation/recession, ΔC_{GA} shown as colour shaded circles at beach locations.
 637 Results shown for sections (d) 144E°-146E°, (e) 146E°-148E° and (f) 148E°-150E°.

638

639 Figure 5: Bar chart showing values of progradation (red) and recession (blue), ΔC_{GA} at each
 640 coastal location of the Bishop-Taylor, et al. (2021) dataset. Values are shown as a function of the
 641 longitude (horizontal axis) and units are m/year. The regions shown in Figure 1 are labelled (a) to
 642 (f).

652 Figure 6: Histograms of progradation/recession rates for each of the coastal sections over the
 653 period 1988 to 2013. (a) $138^{\circ}\text{E}-140^{\circ}\text{E}$, (b) $140^{\circ}\text{E}-142^{\circ}\text{E}$, (c) $142^{\circ}\text{E}-144^{\circ}\text{E}$, (d) $144^{\circ}\text{E}-146^{\circ}\text{E}$, (e)
 654 $146^{\circ}\text{E}-148^{\circ}\text{E}$ and (f) $148^{\circ}\text{E}-150^{\circ}\text{E}$ from west to east.

655
