Abstract

The typical drivers of drought events are lower precipitation and/or higher than normal evaporation. The region’s characteristics may enhance or alleviate the severity of these events. Evaluating the multiple factors influencing droughts and how their combined effect influences droughts requires innovative approaches. This study applies hydrological modelling and a machine learning tool to assess the relationship between hydroclimatic characteristics and the severity of agricultural and hydrological droughts. The Soil Water Assessment Tool (SWAT) is used for hydrological modelling. Model outputs, soil moisture and streamflow are used to calculate the drought indices, namely the Soil Moisture Deficit Index and the Standardized Stream Flow Index. Then, drought indices are utilised to identify the agricultural and hydrological drought events during the analysis period, and the indices categories are employed to describe their severity. From the identified droughts, the number of months for each drought severity category are summed up. Lastly, the Multivariate regression tree technique is applied to assess the relationship between hydroclimatic characteristics (represented by different simulated hydroclimatic parameters) and the severity of agricultural and hydrological droughts (represented by the number of months in different drought severity categories).

25

Our research indicates that multiple parameters influence the severity of agricultural and hydrological droughts in the Cesar River Basin. The upper part of the river valley is very susceptible to agricultural and hydrological drought. Precipitation shortfalls and high potential evapotranspiration drive severe agricultural drought. Limited precipitation influences severe hydrological drought. In the middle part of the river, inadequate rainfall partitioning and an unbalanced water cycle that favours water loss through percolation and evapotranspiration cause severe agricultural and hydrological drought conditions. Finally, droughts are moderate in the basin’s southern part (Zapatosá marsh and the Serranía del Perijá foothills). Moderate exposure

30

to agricultural and hydrological droughts is related to the capacity of the subbasins to retain water, which lowers evapotranspiration losses and promotes percolation. Results show that the presented methodology, combining hydrological modelling and a machine learning tool, provides valuable information about the interplay between the hydroclimatic factors that influence drought severity in the Cesar River basin.

1 Introduction

Projections indicate that drought frequency, severity and duration are expected to increase globally in the twenty-first century (UNDRR, 2021). Upcoming soil moisture drought scenarios predict statically significant, large-scale drying, especially in scenarios with strong radiative forcing in Central America and tropical South America (Lu et al., 2019). A similar trend is predicted for hydrological drought severity, which is expected to increase by the end of the twenty-first century, with regional hotspots in central and western Europe and South America, where the frequency of hydrological drought may increase by more than 20 % (Prudhomme et al., 2014). The intensification of drought characteristics (in combination with other factors) could force the migration of up to 216 million people by 2050 (The World Bank, 2021), increase wildfire risk and tree mortality, and negatively affect regional air quality, among other ecosystem impacts (Vicente-Serrano et al., 2020).

It is essential that we better understand drought drivers if we are to foster preparedness and resilience to projected drought events. Remarkable progress has been achieved in understanding drought propagation through the hydrological cycle (Van Loon et al., 2012). Drought occurs due to climatic extremes, which may be enhanced or alleviated by region characteristics and anthropogenic influence (Hao et al., 2022; Seneviratne et al., 2012; Tijdeman et al., 2018). Typically, droughts are triggered by atmospheric circulation and weather systems that combine to cause lower precipitation and/or higher than normal evaporation in a region (Destouni & Verrot, 2014; Sheffield & Wood, 2011a). Reduced precipitation leads to a decrease in soil moisture, causing agricultural drought. When soil moisture depletion is high, it is restored in the wet season, thus reducing subsurface flow and groundwater recharge and giving rise to hydrological drought (Iglesias et al., 2018). Regional characteristics such as soil type, elevation, slope, vegetation cover, drainage networks, water bodies and groundwater systems play a relevant role in response to the climate anomalies that affect drought propagation and contribute to different levels of agricultural and hydrological drought (Sheffield & Wood, 2011a; Zhang et al., 2022). Equally important, human interventions in the hydrological cycle (e.g. reservoirs, water diversion, deforestation, over-pumping groundwater, overgrazing, urbanisation) can reduce water supplies, triggering a drought situation or exacerbating a climate-driven drought (Rangecroft et al., 2019; Wang et al., 2021).

Drought planning also uses research progress on drought characterisation. Using drought indices is a widespread methodology for drought characterisation. (Zargar et al., 2011). Drought indices are computed numerical representations of drought severity (Hao & Singh, 2015; Keyantash & Dracup, 2002). Severity refers to the drought strength, also described as the deficit degree

(Cavus & Aksoy, 2020), soil moisture deficit in the case of agricultural droughts and streamflow deficit in the case of hydrological droughts. Generally, severity is divided into different categories (e.g. moderate, severe, extreme), providing a qualitative assessment of the drought state in a region during a given period. Drought indices (and their categories) are crucial for tracking or anticipating drought-related damage and impacts (WMO & GWP, 2016).

Despite remarkable progress achieved in understanding the drought-generating process and drought characterisation, there is still a need for studies that assess the complex interplay between the different drivers of droughts and how their combined effect influences drought characteristics (e.g. duration, severity, intensity) (Valiya Veetil & Mishra, 2020). Previous studies focus on the influence of one driver (Margariti et al., 2019; Mastrotheodoros et al., 2020; D. Shah et al., 2021; Xu et al., 2019), and some of the methodologies applied cannot adequately address the non-linear relationship between climate, basin processes and droughts characteristics (Peña-Gallardo et al., 2019; Saft et al., 2016; Van Loon, 2015).

We have found two studies employing machine learning to assess the non-linear relationship between climate and basin processes and droughts (Konapala & Mishra, 2020; Valiya Veetil & Mishra, 2020). The studies reported relevant findings on the parameters driving droughts; however, the selected techniques showed a limitation for the drought analysis since they allow only one output variable. In both cases, it was necessary to apply the chosen technique multiple times to find the relationships between hydroclimatic parameters and the different categories of the evaluated drought characteristics. For example, Valiya Veetil et al. (2020) used a classification and regression tree (CART) to identify the variables influencing drought duration. CART allows one output variable; then, the authors applied the approach three times to evaluate the variables influencing short-term, medium-term and long-term drought events. Meanwhile, Konapala et al. (2020) used a random forest (RF) algorithm to identify the climate and basin parameters influencing the characteristics (duration, frequency and intensity) of three different drought regimes (long duration and mild intensity, moderate duration and intensity, short duration and high intensity). As the core of RF is a decision tree that allows one output variable (in this case, each characteristic of each drought regime), the authors repeated the procedure nine times, one for each drought regime and characteristic.

The aforementioned research shows the potential of machine learning techniques for drought-related analysis; nevertheless, it also suggests that assessing the parameters driving drought characteristics requires techniques capable of simultaneously handling the different categories of drought characteristics. Commonly used in ecology to relate independent environmental conditions to populations of multiple species, the Multivariate Regression Tree (MVRT) arises as a suitable technique for this purpose. MVRT is a constrained clustering technique that links explanatory variables to multiple response variables while maintaining the individual characteristics of the responses. Significantly, the technique does not assume a linear relationship between explanatory and response variables. Furthermore, it allows for the so-called “interpretable machine learning” algorithms that make decisions and predictions understandable to humans (Molnar, 2022). MVRT interpretably is a relevant

attribute for drought researchers and planners since it allows them to identify the parameters influencing severe (or mild) drought conditions.

100 To understand the relationship between the drivers of droughts and the individual categories of agricultural and hydrological droughts severity, this study employs a methodology that consists of three steps. The first is hydrological modelling. We used SWAT to simulate the hydroclimatic parameters required for analysing droughts and applying the MVRT approach. The Second is the analysis of droughts. SWAT outputs, soil moisture and streamflow are used to calculate the drought indices, i.e., the Soil Moisture Deficit Index (SMDI) and the Standardized Stream Flow Index (SSI). Drought indices are utilised to identify
105 the agricultural and hydrological drought events in the analysis period. Then, we calculate the months for each drought severity category during the observed droughts. Finally, the MVRT approach is applied to assess the relationship between hydroclimatic characteristics (represented by the simulated parameters in each subbasin) and drought severity categories (represented by the total number of months for each drought severity category in each subbasin). The analyses for agricultural and hydrological droughts were conducted separately; thus, two MVRTs were obtained. A concrete application of this methodology is developed
110 in the Cesar River basin (Colombia, South America).

2 Study location and methods

2.1 Case study

Figure 1 presents the Cesar River basin's location, topography and land use. The basin is located between 72°53'W 74°04'W and 10°52'00"N 7°41'00"N latitude (Colombia). It extends for an area of 22,312 km². The basin's topography is defined in
115 three distinct climatic regions (Universidad del Atlantico, 2014). In the north is La Sierra Nevada de Santa Marta. This sector is characterised by steeply sloped mountains reaching up to 5,700 meters above sea level (masl). The temperature ranges from 3°C to 6°C, and the mean annual precipitation is 1,000 mm. In the east is La Serranía del Perijá. This mountainous area is an extension of the eastern branch of the Andes range. In this sector, the altitude ranges from 1,000 to 2,000 masl. The average temperature is 24°C, and the average annual precipitation varies from 1,000 mm to 2,000 mm. Lastly, the valley of the Cesar
120 River and the Zapatosa marsh are in the west and south of the basin, respectively. The valley is characterised by flat topography and a complex system of marshes formed by the Cesar River floodplains and its confluence with the Magdalena River. The average temperature is 28°C, and the mean annual precipitation is 1,500 mm. At the basin, the annual rainfall pattern presents a dry season from December to April, followed by a rainy season from April to May. In the intermediate period from June to July, precipitation decreases. The main rainfall events occur between August and November.

125

The predominant land use is pasture, followed by agriculture (Universidad del Atlantico, 2014). The primary land use in La Sierra Nevada foothills is pastures for cattle farming. In La Serranía del Perijá, the high-altitude areas are covered by forests in very good condition; at the lower altitudes, the principal land use is agriculture, particularly subsistence crops. The Cesar

130 River valley's soils are rich in nutrients, providing favourable conditions for agriculture. The riverbanks are covered by forests with low tree density.

The Zapatos marsh is recognised as one of the most important wetlands in the country, and considering the relevance of this ecosystem, it was declared a Ramsar site in 2018. Nevertheless, the region is threatened by high water demand of monocrops and overexploitation of its forest resources. In addition, climate change projections indicate that the basin's temperature may increase by 2.7°C, and precipitation may reduce by 10 % by 2070 (Universidad del Magdalena et al., 2017). Accordingly, 135 multiple initiatives are oriented to improve water management and create resilience to hydroclimatic extremes (Ministerio de Ambiente y Desarrollo Sostenible (Colombia), 2015).

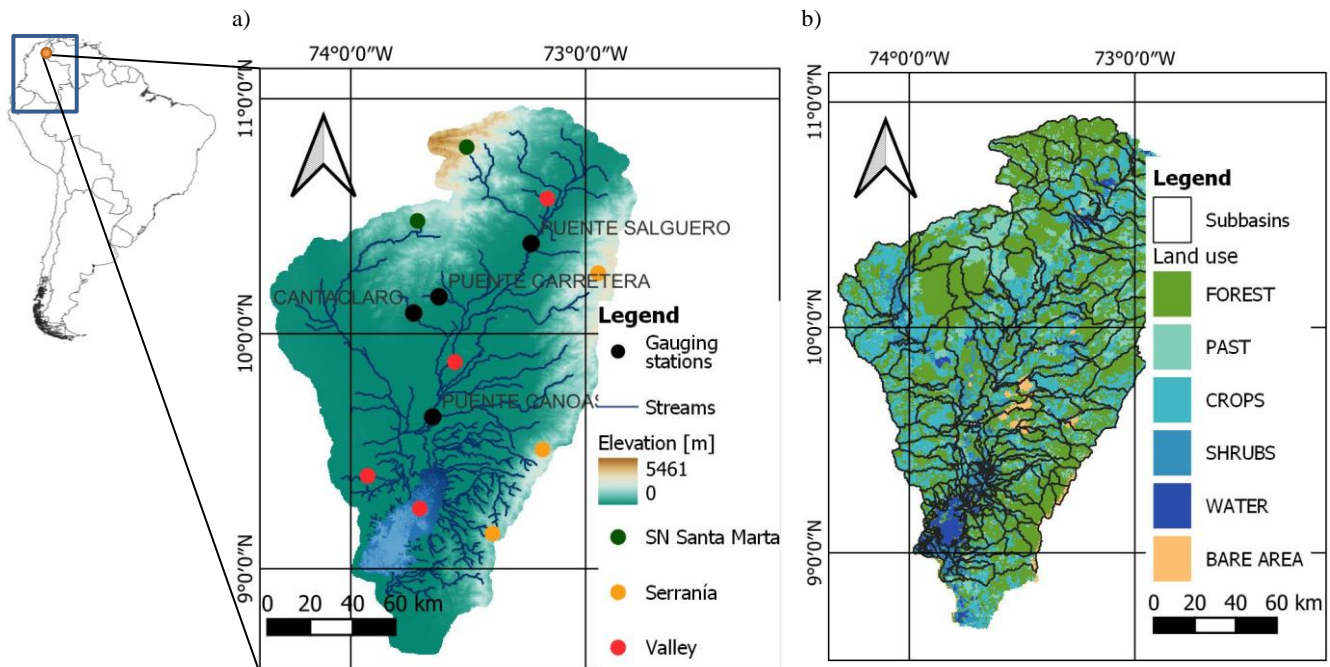

Figure 1 Cesar River basin: a) topography and b) land use.

2.2 Methods

140 Figure 2 illustrates the three steps methodology applied in this study. Section 2.2.1 describes the hydrological modelling, and 2.2.2 the drought analysis. Section 2.2.3 presents the application of the MVRT technique.

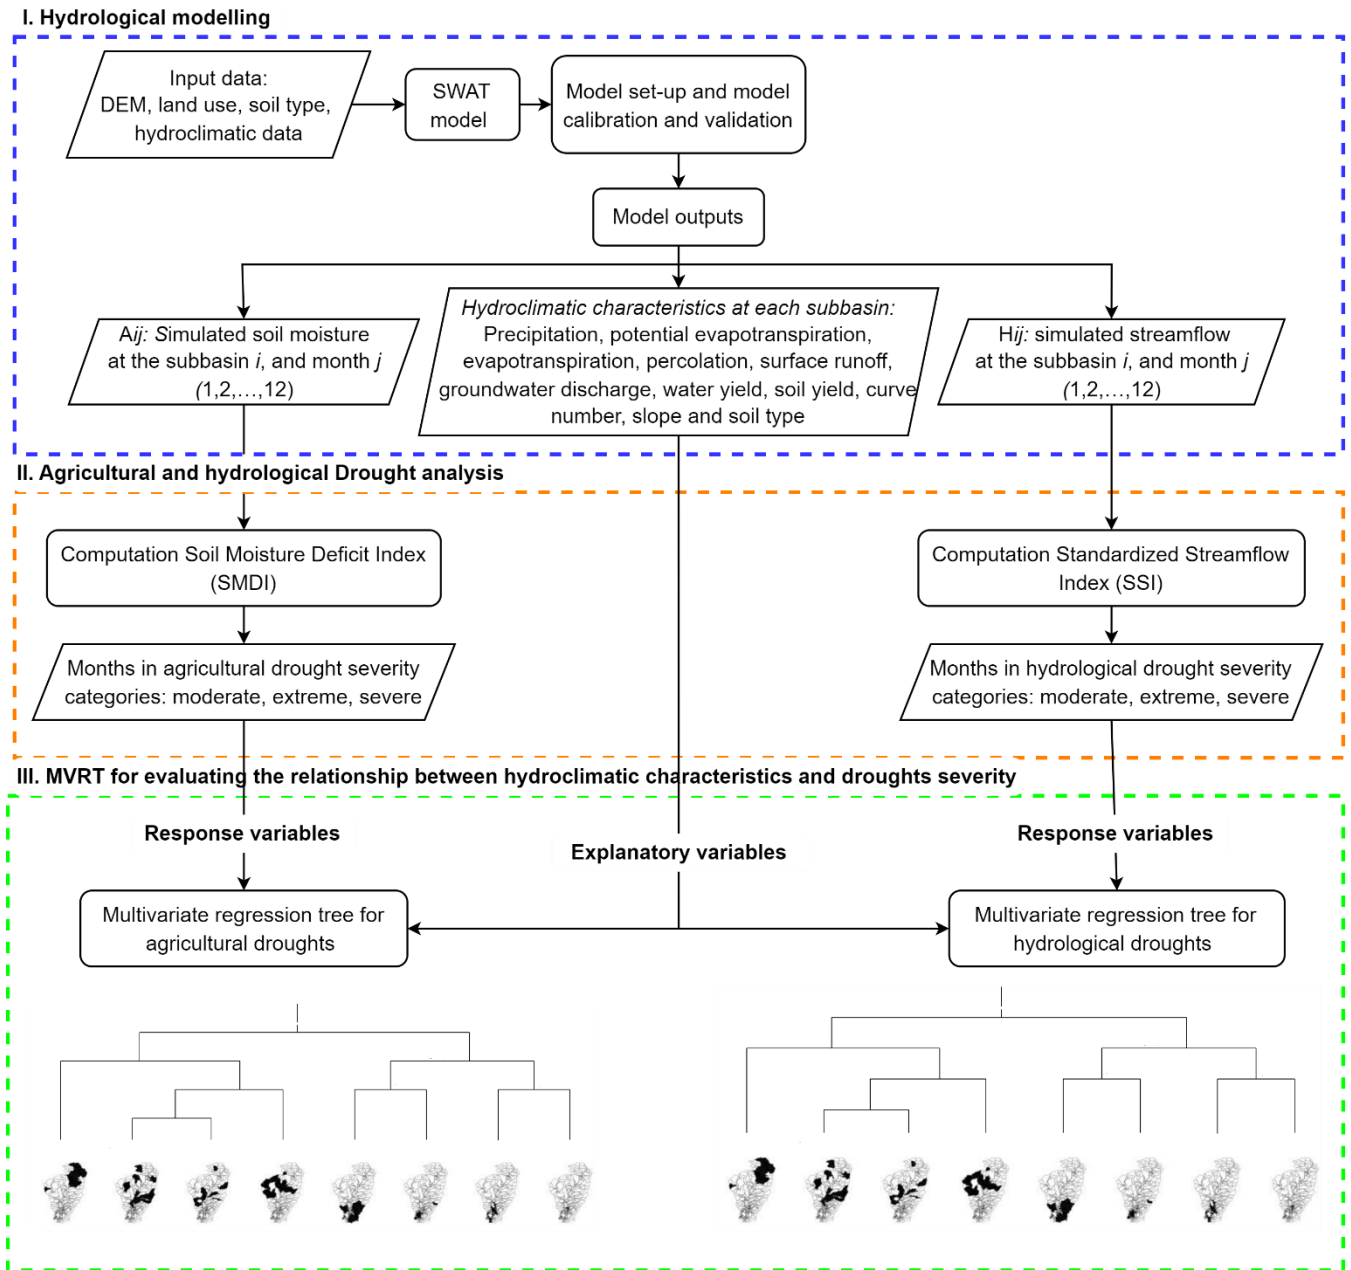

Figure 2 Flow chart of the methodology.

145 2.2.1 Hydrological modelling

A SWAT model with an ArcSWAT extension was used to develop the hydrological model of the Cesar River. SWAT is a continuous-time, semi-distributed, process-based river watershed-scale model developed by The Agricultural Research Service of the United States Department of Agriculture (ARS-USDA). The model is designed to simulate the quality and quantity of

surface and groundwater and predict the environmental impacts of land management and climate change (Neitsch et al., 2011).
 150 In SWAT, the basin area up to the outlet point is divided into several subbasins. Each subbasin is further split into multiple
 Hydrological Response Units (HRU), which are areas within the subbasin with common combinations of land cover, soil type
 and slope (Arnold et al., 2012).

Model setup

The model was built for the period from 1987 to 2018. The Cesar River basin was divided into 313 subbasins with a median
 155 area of 50 km². Four slope classes were set for the HRUs generation: flat (0–2%), gentle (2–10%), steep (10–35%) and
 considerably steep (>36%) (GEF et al., 2020, 2021). The following methods were used to model the principal hydrological
 processes: the soil conservation services-curve number (SCS-CN) was used to simulate surface runoff; potential
 evapotranspiration was estimated using the Hargreaves method; and water was routed through the channel network using the
 variable storage routing method. The details and sources of the SWAT model input data are presented in Table 1.

160

Table 1. SWAT model input data

Data type	Details	Source
Digital elevation model	25 × 25 m	Dataset ALOS PALSAR L1.0, Cartography 1:25000 Geographic Institute Agustín Codazzi (IGAC), Colombia
Soil map	300 × 300 m	Soil profiles Project GEF Magdalena–Cauca VIVE, GEF, BID, Fundación Natura, Colombia
Land use map	25 × 25 m	Land use map Geographic Institute Agustín Codazzi (IGAC), Colombia
Rainfall and temperature daily data	Period 1985–2018 (34 years)	Institute of Hydrology, Meteorology and Environmental Studies (IDEAM), Colombia

Model calibration and validation

We used the SWAT-CUP software package with Sequential Uncertainty Fitting version 2 (SUFI-2) to evaluate the model's
 performance in simulating streamflow for automatic model calibration and validation. With SUFI-2, parameter sensitivities
 165 are determined by applying a multiple regression approach, which regresses the parameters sampled via a Latin hypercube
 technique against the objective function values (Abbaspour et al., 2018).

Based on expert judgment and the available literature (Arnold et al., 2012; ASABE, 2017), the following SWAT parameters
 were used in the calibration and validation process: baseflow alpha factor (ALPHA_BF), effective hydraulic conductivity in
 170 main channel alluvium (CH_K), Manning's value for the main channel (CH_N2), SCS runoff curve number for moisture
 condition II (CN2), soil evaporation compensation factor (ESCO), groundwater delay (GW_DELAY), threshold depth of water

in the shallow aquifer required for return flow to occur (GWQMN), deep aquifer percolation fraction (RCHRG_DP), threshold depth of water in the shallow aquifer for percolation to the deep aquifer to occur (REVAPMN) and available water capacity of the soil layer (SOL_AWC).

175

The model was calibrated from 1985 to 2002 and validated from 2003 to 2018 using the streamflow series from four stream gauges (Figure 1). The source of the discharge data is the Institute of Hydrology, Meteorology and Environmental Studies (IDEAM), Colombia. The first two years were used as a warming-up period in both cases. Thus, performance indicators were calculated for 1987 to 2002 (calibration) and 2005 to 2018 (validation). The model was evaluated using the Nash-Sutcliffe
180 Efficiency (NSE) and percent bias (PBIAS), represented by Eq. 1 and Eq. 2, respectively:

$$NSE = 1 - \frac{\sum_{i=1}^N (O_i - P_i)^2}{\sum_{i=1}^N (O_i - \bar{O})^2} \quad 1$$

$$PBIAS = \frac{\sum_{i=1}^N (O_i - P_i) \times 100}{\sum_{i=1}^N O_i} \quad 2$$

where O_i is the observed data, P_i the predicted data, \bar{O} the mean of the observed data and N the number of observations during the simulation period.

185 The NSE represents a dimensionless indicator ranging from $-\infty$ to 1, with 1 representing a perfect match between the observed and simulated values (Moriasi et al., 2007). The PBIAS measures the average tendency of the simulated values to be larger or smaller than the observed values. A low PBIAS magnitude indicates accurate model simulation (Moriasi et al., 2007).

2.2.2 Agricultural and hydrological drought analysis

The present study used the soil moisture deficit index (SMDI) to analyse agricultural droughts. We chose this index since it
190 was developed to use simulated soil moisture as input parameter (Narasimhan & Srinivasan, 2005). SWAT calculates the soil water content of the entire soil profile. According to the soil profiles used to elaborate the soil map, three soil layers were identified in the Cesar River basin. The soil layers' thickness (vertical distance from the surface) varies. The first layer reaches up to 350 mm, the second 1000 mm, and the third 1500 mm.

195 The computation procedure to determine the soil moisture deficit used the long-term soil moisture characteristics and the soil moisture conditions during the drought period. The indicator was scaled between -4 to 4 to allow the spatial comparison of the drought index, regardless of climatic characteristics (Narasimhan & Srinivasan, 2005). Negative values of SMDI indicate dry periods, while positive values indicate wet periods (compared to the region's normal conditions). Per the SMDI, agricultural drought severity was divided into three categories: moderate drought (SMDI -2.0 to -2.99), severe drought (SMDI -3.0 to -
200 3.99) and extreme drought (SMDI -4 or less). The following procedure was applied to compute the SMDI at each subbasin:

$$SD_{ij} = \frac{SW_{ij} - MSW_j}{MSW_j - minSW_j} \times 100, \quad \text{if } SW_{ij} \leq MSW_j \quad 3$$

$$SD_{ij} = \frac{SW_{ij} - MSW_j}{maxSW_j - MSW_j} \times 100, \quad \text{if } SW_{ij} > MSW_j \quad 4$$

where SD_j is the soil moisture deficit (%), SW_j is the monthly soil water available in the soil profile (mm) and MSW_j , $maxSW_j$ and $minSW_j$ are long-term median, maximum and minimum soil water available in the soil profile (mm), respectively, ($i = 1987 - 2018$ and $j = 1 - 12$).

205

The $SMDI_j$ of any given month was calculated using Eq. 5:

$$SMDI_j = 0.5 \times SMDI_{j-1} + \frac{SD_j}{50} \quad 5$$

where $SMDI_{j-1}$ is the SMDI from the previous month.

210 SMDI was not calculated for the subbasins that correspond to the Zapatos marsh. In these subbasins the predominant land cover is water. See Figure 5.

We used a standardised streamflow index (SSI) to represent hydrological droughts. The indicator was introduced by Modarres (2007) and further investigated by Vicente-Serrano et al. (2011). The index is statically analogous to the commonly used standardised precipitation index (SPI) introduced by Mckee et al. (1993). SSI values mainly range from -2.0 (extremely dry) to 2.0 (extremely wet), and hydrological drought severity is divided into three categories: moderate drought (SSI -1.0 to -1.49), severe drought (SSI -1.5 to -1.99) and extreme drought (SSI -2.0 or less). The procedure to calculate SSI consists of converting streamflow values to standardised anomalies (i.e. z-scores). To this aim, the monthly simulated streamflow at each subbasin in the analysis period (1987 to 2018) was fitted to the gamma probability distribution function.

220

SMDI and SSI were calculated monthly using the simulated soil water and streamflow values at each subbasin. The drought events during the period of analysis were then identified. A drought (agricultural or hydrological) event was assumed to occur in the basin when a number of subbasins (covering at least 30 % of the basin's total area) were in a moderate drought state for at least two consecutive time steps (i.e. in this study month). According to the spatial and temporal thresholds, a drought event began when both conditions were met and continued until one of them failed to be met. It is worth highlighting that the minimal extension of a drought is not defined, but it is accepted that droughts typically occur on a large scale (Sheffield & Wood, 2011b). Setting a spatial threshold is a common practice to maintain a minimum drought-affected and prevent identifying isolated areas experiencing dry spells as drought events (Brunner et al., 2021). Regarding the temporal threshold, it was used

225

to avoid including sort periods of water shortage and minor and flash droughts in the analysis. These are events that occur
230 within days or weeks (J. Shah et al., 2022)

2.2.3 Multivariate regression tree approach for evaluating the relationships between hydroclimatic characteristics and droughts severity

MVRT is an extension of the popular regression tree (Breiman, 2001), but it differs in that it allows for multiple outputs (see
De'ath(2002). It recursively splits a quantitative response variable (predictand, output) controlled by a set of numerical or
235 categorical explanatory variables (predictors, input). The technique approach yields a set of non-linear models, each a piece-
wise linear regression model (of zero order). An MVRT result is a tree whose terminal groups (leaves) of instances (input-
output vectors) comprise subsets of samples selected to minimise the within-group sums of squares. Each successive split is
given by a threshold value of the explanatory variables (Borcard et al., 2018). MVRT is applied to dataset exploration,
description and prediction (De'ath, 2002). In this study, the explanatory variables are the hydroclimatic parameters at each
240 subbasin, represented by the average value of each parameter during the analysis period (1987 to 2018). The multivariate
response is the number of months observed in the three drought severity categories (moderate, severe and extreme) at each
subbasin. The analyses for agricultural and hydrological droughts were conducted separately; thus, two MVRTs were obtained.

The following MVRT attributes are relevant for this study. First, MVRT can capture the non-linear interactions between the
245 parameters influencing droughts and their severity. Second, the technique can handle numerical and categorical hydroclimatic
parameters influencing drought severity (explanatory variables). Third, MVRT's capability to handle multiple outputs allowed
us to evaluate the influence of the hydroclimatic parameters on moderate, severe and extreme drought conditions
simultaneously (response variables). Simultaneous analysis of different drought categories provides a comprehensive
understanding of the drought-generating process and the factors influencing severe (or mild) drought conditions. Fourth,
250 MVRT results can be easily visualised and interpreted. The resulting tree structure provides a clear representation of the
relationship between the drivers of droughts and the severity of agricultural and hydrological droughts.

For building the MVRT, R software was used, namely, package mvpart. Before the analysis, the sets of explanatory and
response variables were transformed to compare the descriptors measured in different units and to modify the variables'
255 weights. The matrix of explanatory variables was standardised to a mean of zero and a standard deviation of one. The matrix
of response variables was standardised by the column maximum, then again by the row total (Wisconsin double
standardisation).

Datasets

Set of explanatory variables

260 To select the set of explanatory variables, we used the outcomes of previous studies on governing drivers of droughts (Sheffield & Wood, 2011a; Zhang et al., 2022). Table 2 describes the eleven parameters selected as the potential drivers of droughts. The used values correspond to the parameters' average in the analysis period (1987 to 2018). The averages were computed using the SWAT model results at each subbasin. We used the dominant category at each subbasin for the curve number, the slope, and the soil type (categorical variables).

265

Table 2. Explanatory variables used in MVRT

Hydroclimatic parameter	Abbreviation	Unit	Definition
Precipitation	PRECP	mm	Average precipitation at each subbasin
Potential evapotranspiration	PET	mm	Average potential evapotranspiration at each subbasin
Evapotranspiration	ET	mm	Average actual evapotranspiration at each subbasin
Percolation	PERC	mm	Average percolation past the root zone
Surface runoff	SURFQ	mm	Average surface contribution to the streamflow at each subbasin
Groundwater	GRWQ	mm	Average groundwater contribution to the streamflow at each subbasin
Water yield	WYLD	mm	Average amount of water that leaves the subbasin and contributes to the streamflow at each subbasin
Sediment yield	SYLD	metric tons/ha	Average sediment from the subbasin transported into the reach
Curve number	CN	–	Dominant curve number at each subbasin
Slope	SLP	–	Dominant slope at each subbasin
Hydrologic soil group	STY	–	Dominant hydrologic soil group (A, B, C, and D) at each subbasin. The soil hydrologic groups refer to the soil's infiltration characteristics. Properties of each soil type can be found in USDA (2007)

Set of response variables

We used the drought analysis outcomes to define the response variables (Table 3). Following the methodology presented in 2.2.2, we identified the agricultural and hydrological drought events during the analysed period. After identifying the drought events, we counted the months for each drought severity category at each subbasin. The observed months for each one of the three drought categories were used as response variables. The analyses for agricultural and hydrological droughts were conducted separately; thus, two sets of response variables were obtained.

270

Table 3. Response variables used in MVRT

Drought category	Abbreviation	Unit	Definition
Moderate agricultural/hydrological drought	MOD	month	Number of months in the moderate agricultural drought category during the drought events identified in the simulation period at each subbasin
Severe agricultural/hydrological drought	SEV	month	Number of months in the severe agricultural drought category during the drought events identified in the simulation period at each subbasin
Extreme agricultural/hydrological drought	EXT	month	Number of months in the extreme agricultural drought category during the drought events identified in the simulation period at each subbasin

275 **Building the MVRT**

Building the MVRT consisted of two processes: (1) the constrained partitioning of the data, and (2) the cross-validation of the results. The mvpart package run both processes in parallel. The two procedures are briefly explained below, and a more detailed description can be found in Borcard et al. (2018).

Constrained partitioning of the data

280 The data partitioning consisted of three steps. First, for each explanatory variable were generated all possible partitions of the sites (subbasins) into two groups. Second, for each partition, it was calculated the resulting sum of within-group sums of squared distances to the group means for the response data (within-group SS). Within-group SS is equivalent to standard deviation. Lastly, the partition into two groups to minimise the within-group SS and the threshold value/level of the explanatory variable was retained. These steps were repeated within the two previously established subgroups until all the objects formed
285 their own groups. For each tree that was computed, the relative error was calculated as the sum of the within-group SS of all leaves divided by the overall SS of the data. This procedure for MVRT is equivalent to the one originally proposed by Breiman (2001) for his regression tree technique.

Cross-validation of the partitions and tree pruning

A cross-validation procedure was used to prune the tree and identify the optimal tree size (Kuhn & Johnson, 2013; Legendre
290 & Legendre, 2012). The cross-validation procedure was performed automatically using mvpart. Per this procedure, the data was randomly divided into roughly equal-sized test groups. Each test group was held out in turn while the tree was fitted using the remaining groups. The distances between the centroids of the objects at tree leaves and each object of the test group were then calculated. Finally, the objects of the test group were allocated to the closest leaf of the constructed tree. An overall relative error statistic (relative cross-validation error, CVRE) was calculated for each group using all n objects, per Eq. 6:

$$CVRE_{(k)} = \frac{\sum_{i=1}^n \sum_{j=1}^p (y_{ij(k)} - \hat{y}_{j(k)})^2}{\sum_{i=1}^n \sum_{j=1}^p (y_{ij} - \bar{y}_j)^2}$$

295

where $y_{ij(k)}$ is the value of variable j for object i belonging to test group k , $\hat{y}_{j(k)}$ is the value of that same variable at the centroid of the leaf closest to object i , and the denominator is the overall sum of the Y data squares.

This cross-validation process was repeated several times for consecutive and independent divisions of the data into test groups. For each group, the mean and standard deviation of all CVRE were computed. The CVRE varied from 0 for perfect predictors to close to 1 for poor predictors (as error increases, CVRE increases indefinitely). Among the `mvpart` function arguments, we used ten cross-validation groups (function argument, `xval = 10`) and 100 iterations (function argument `xmult = 100`). The tree was selected using interactive cross-validation (function argument `xv = 'pick'`).

To choose the size of the tree that retained the most descriptive partition, we used the approach suggested by De'ath (2002). According to the author the tree with the smallest CVRE offers the best combination of explanatory power and interpretability. Once the tree was built, the proportion of explained variance (EV) was calculated as $1 - RE_{tree}$ (tree relative error) (Cannon, 2012).

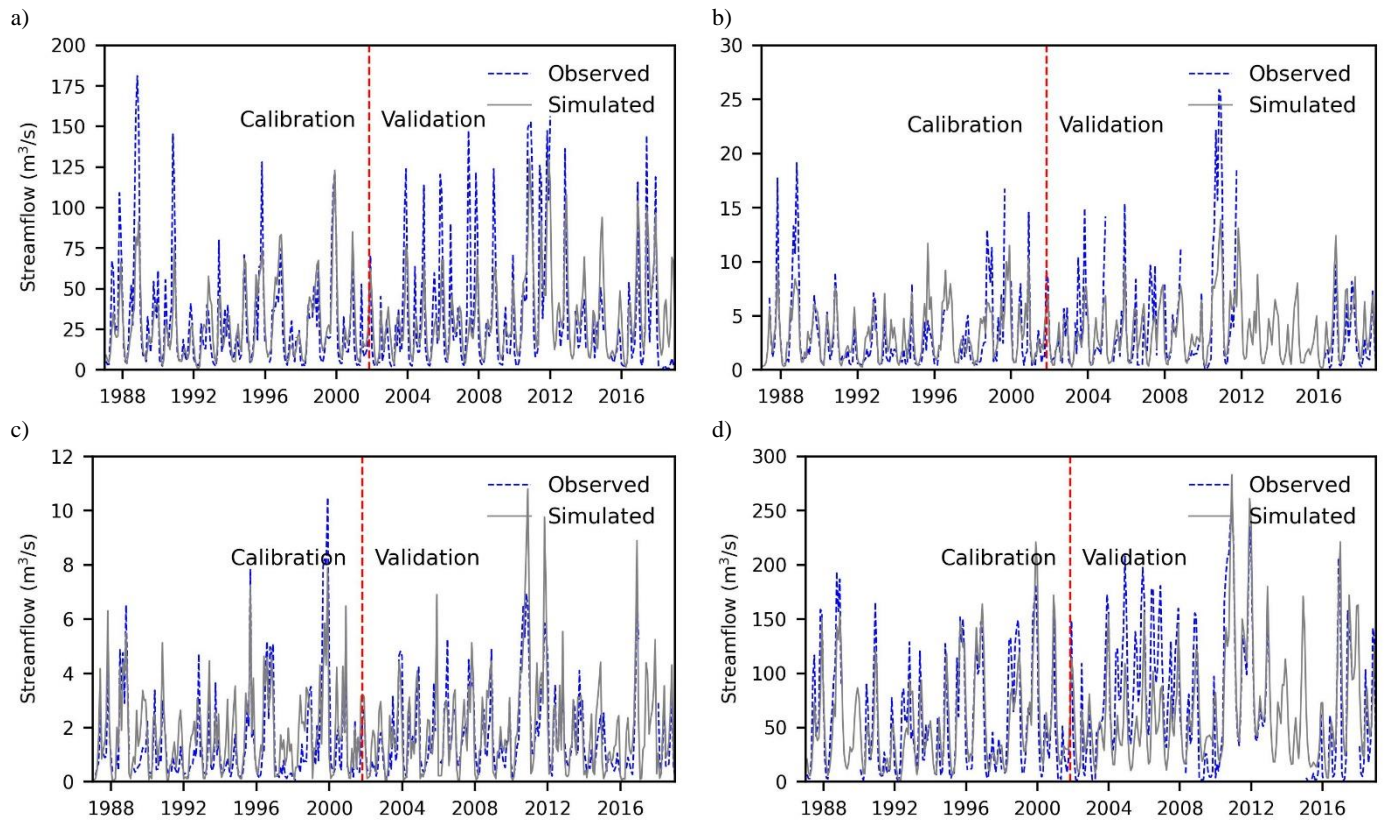

3 Results

3.1 SWAT model calibration and validation

Table 4 summarises the calibration and validation performance indicators for the SWAT model at each gauging station. The calibration and validation models simulated monthly stream flows with NSE values equal to or greater than 0.50 and relatively low PBIAS values (GEF et al., 2020, 2021). According to the performance ratings for calibrating and validating hydrological models, NSE and PBIAS values indicated that the model was appropriate for simulating streamflow (Moriassi et al., 2007). Figure 3 presents the model hydrographs at each gauging station for the calibration and validation periods. The locations of the stations can be found in Figure 1.

Table 4. SWAT model performance simulating streamflow

Gauging station	Calibration		Validation	
	NSE	PBIAS [%]	NSE	PBIAS [%]
Puente Salguero	0.61	4.28	0.52	-8.3
Puente Carretera	0.50	-5.34	0.52	7.6
Cantaclaro	0.58	-11.30	0.50	-11.7
Puente Canoas	0.70	-1.34	0.57	10.64

320 **Figure 3** Monthly calibration and validation for streamflow at: a) Puente Salguero, b) Puente Carretera, c) Cantaclaro and d) Puente Canoas.

Since the study focuses on droughts, the model performance simulating streamflow in the dry season was analysed separately. Performance indicators were calculated for the period corresponding to the basin's dry season (December to March). The intermediate period of precipitation decrease from June to July was also included in this analysis. Table 5 summarises the calibration and validation performance indicators in the dry season. According to the rating guidelines, the model performance
 325 simulating streamflow in the dry season is satisfactory (ASABE, 2017).

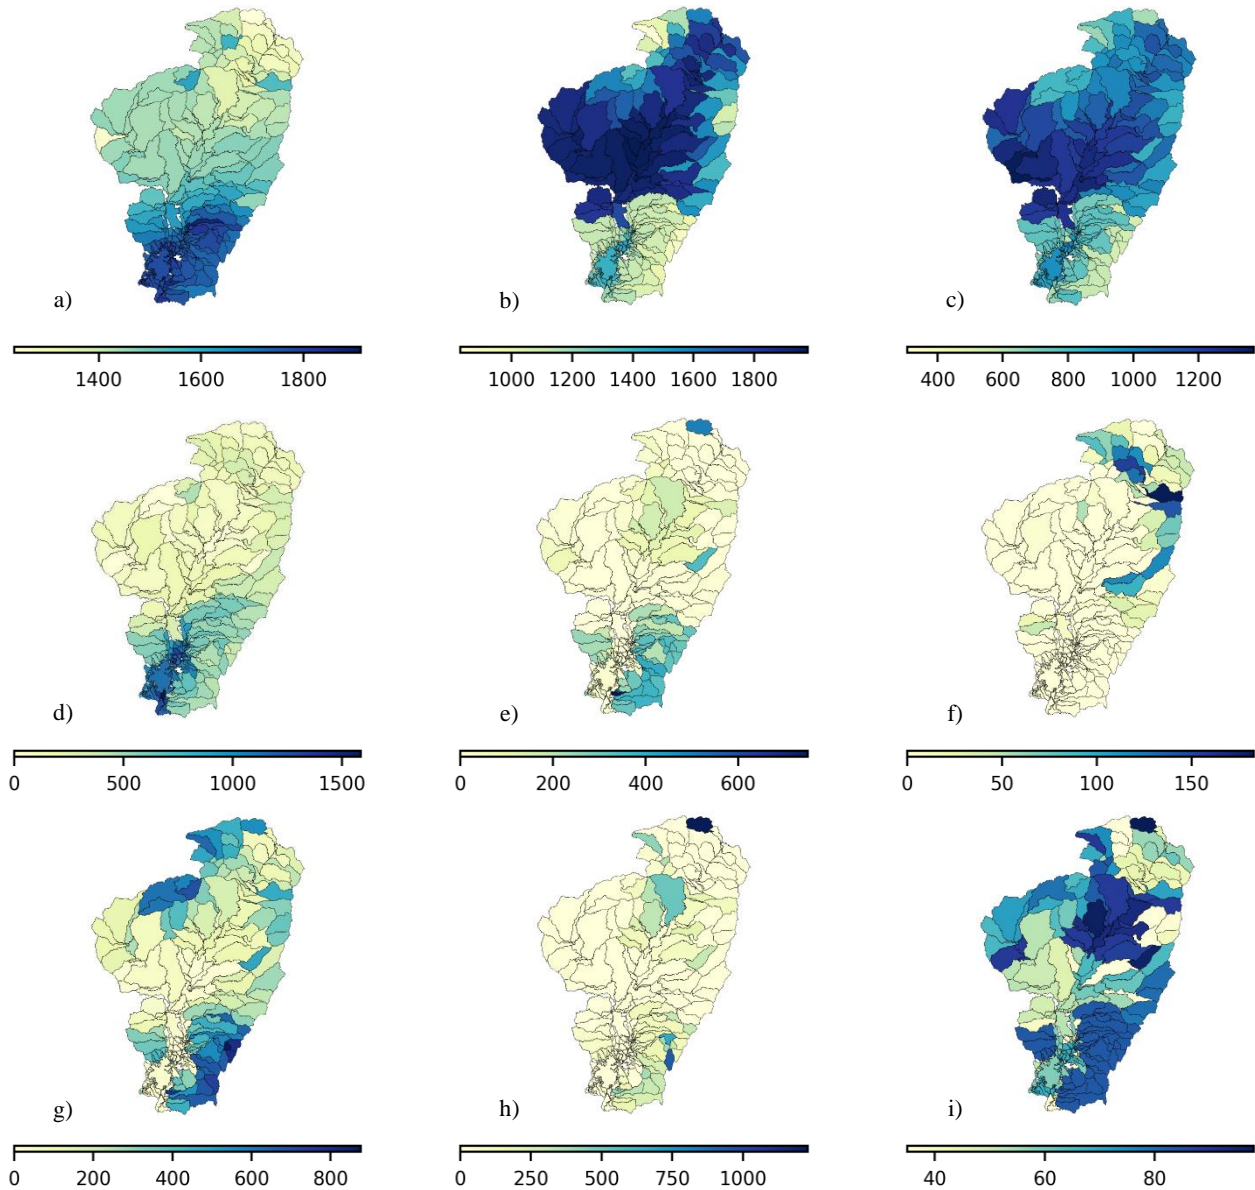

Table 5. SWAT model performance simulating flows in the dry season.

Gauging station	Calibration		Validation	
	NSE	PBIAS [%]	NSE	PBIAS [%]
Puente Salguero	0.65	-19.4	0.53	-21.3
Puente Carretera	0.67	-15.3	0.53	17.2
Cantaclaro	0.67	-3.6	0.58	16.3
Puente Canoas	0.55	-15.7	0.60	-13.5

330 3.2 Hydroclimatic drivers of droughts

Figure 4 presents the numerical and categorical hydroclimatic parameters used as potential drivers of droughts. Figure 4a to h presents the multi-annual average of the numerical hydroclimatic drivers of droughts at each subbasin. The average was calculated using the hydrological model's results during the simulation period (1987 to 2018). Figure 4i to k presents the categorical drivers: the curve number, slope and soil type. The dominant category at each subbasin is shown in Figure 4i to k.

335 The dataset of explanatory variables was created from the values presented in Figure 4.

Figure 4 Average value of hydroclimatic parameters during the simulation period at each subbasin: a) precipitation in mm, b) potential evapotranspiration in mm, c) actual evapotranspiration in mm, d) percolation in mm, e) surface runoff in mm, f) groundwater contribution to streamflow in mm, g) water yield in mm, h) sediment yield in metric tons/ha, i) curve number, j) slope and k) soil type.

340 3.3 Drought events during the simulation period and their duration

Following the methodology described in 2.2.2, we identified the drought events in the analysis period. Table 6 shows the dates and durations of these events. The identified drought events in the simulation period were in good agreement with the chronology of drought events in Colombia described at the National Study of Water (Instituto de Hidrología, 2019).

345 **Table 6.** Agricultural and hydrological droughts during the period of analysis

Event	Agricultural droughts		Hydrological droughts	
	Date	Duration [months]	Date	Duration [months]
I	May 1991 – Jun 1992	13	Apr 1991 – May 1992	14
II	Jun 1997 – April 1998	11	Apr 1997 – Feb 1998	11
III	Jun 2001 – Aug 2001	3	May 2001 – Jun 2001	2
IV	Oct 2009 – Jan 2010	4	Sep 2009 – Nov 2009	3
V	Jun 2014 – Aug 2014	3	Jun 2014 – Jul 2014	2
VI	May 2015 – Jul 2016	15	Apr 2015 – Apr 2016	13

After identifying the agricultural and hydrological drought events, it was possible to determine the number of months for each drought category in each subbasin, as represented in Figures 5 and 6 for agricultural and hydrological droughts, respectively. The results presented in Figures 5 and 6 are the response variables for the MVRT technique.

350

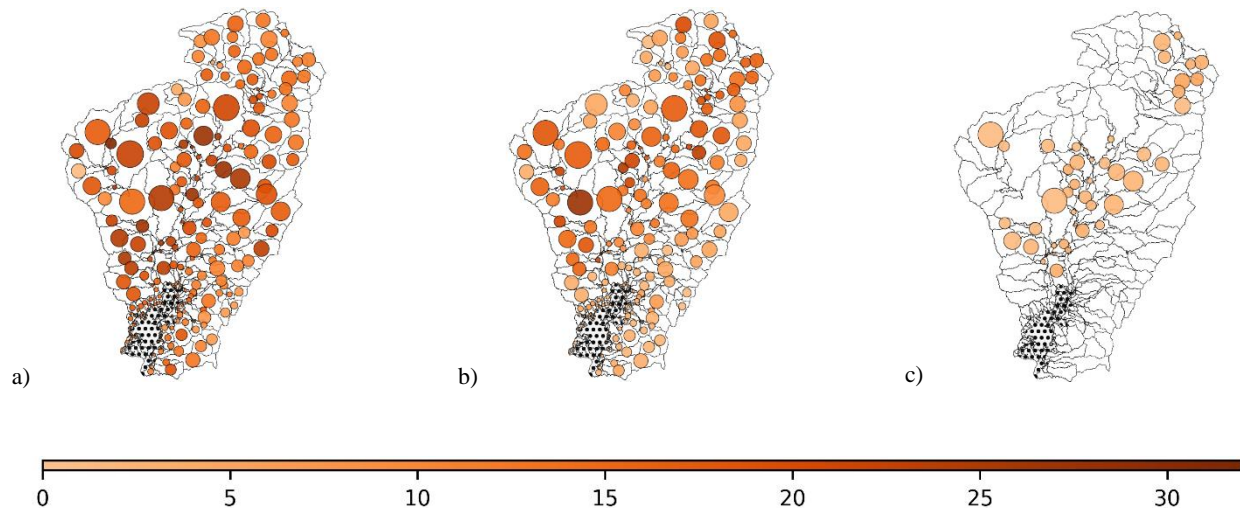

Figure 5 Months counted in each agricultural droughts category: a) moderate, b) severe and c) extreme. SMDI was not calculated in the wetland subbasins (i.e. hatched area).

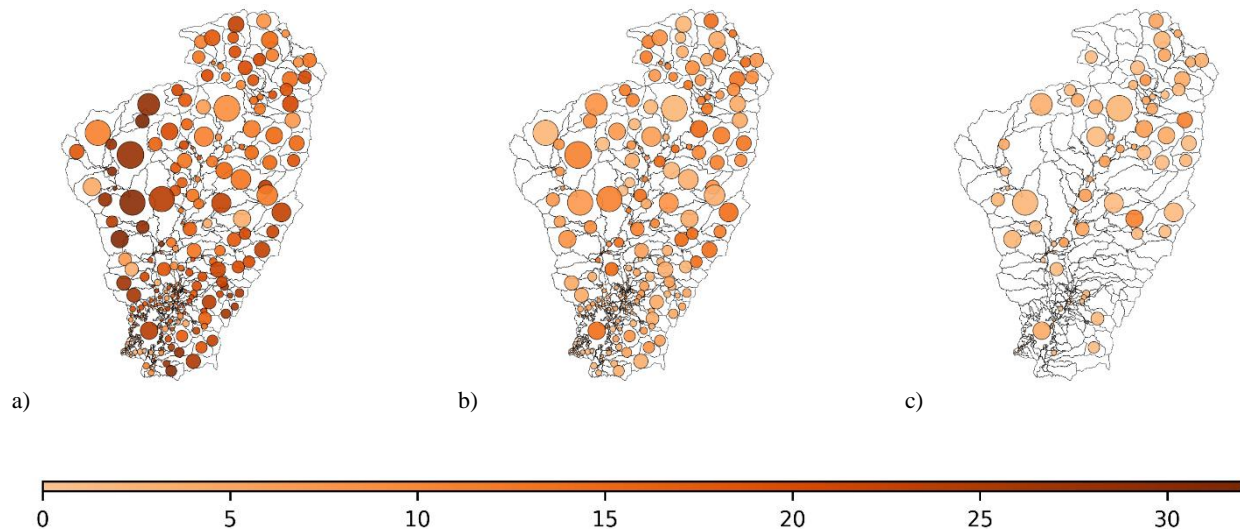

Figure 6 Months counted in the hydrological droughts category: a) moderate, b) severe and c) extreme.

3.4 Multivariate regression tree

355 In this section, we describe the results of the MVRT technique applied to identify the governing drivers of agricultural and hydrological drought severity and the critical thresholds of these drivers.

3.4.1 Drivers of agricultural drought

Figure 7 presents the tree generated by R software, the number of subbasins clustered at each terminal group (variable “ n ”), and the spatial distribution of these subbasins. The tree consists of five levels of split and twelve leaves. The minimum value of the cross-validation error (CVRE = 0.46) was used to select the tree size. The relative error of the MVRT was 0.19, and the EV was 0.81. Figure 8 presents the tree’s numerical output: namely, the number of months for each drought category. The scattering of the outputs in each leaf allows us to identify the most susceptible subbasins to agricultural droughts.

The MVRT indicated that actual evapotranspiration was a strong driver of agricultural droughts; it appeared three times at different tree levels of split. The subbasins were split at the first level according to ET (924 mm). At the second level of split, precipitation (1,318 mm) was used for the left branch of the tree and percolation (271 mm) for the right branch. Then, the left branch was recursively split as follows: at the third level, according to potential evapotranspiration (1,888 mm) and evapotranspiration (1,191 mm); at the fourth level, according to evapotranspiration (1,064 mm) and percolation (111 mm); and at the fifth level, according to sediment yield (101 tons/ha). The left branch accounts for seven out of the tree’s twelve leaves. Regarding the right branch, splitting was done according to evapotranspiration (729 mm) and the curve number (67) at the third level and according to the water yield (352 mm) at the last level. In the following, we describe agricultural drought MVRT terminal groups.

Leaf *a* clusters seven subbasins in the north part of the basin. In this area, actual evapotranspiration and potential evapotranspiration were above the basin average, while precipitation was below average (Figure 4c, b and a, respectively). Figure 8a shows that these subbasins experienced the highest number of months in extreme agricultural drought and a median of fifteen months in severe agricultural drought. Leaf *b* clusters two subbasins in the western part of the basin. In this leaf, there are no months in the extreme drought category. The median of months in the moderate and severe agricultural drought categories is ten months, one of the lowest among the terminal groups (Figure 8b).

Leaves *c* and *d* cluster twenty-four and nineteen subbasins, respectively. Leaf *c* groups subbasins located in the upper part of the river course and the basin east. Precipitation was slightly below the basin average in the subbasins located in the north and was close to the average in subbasins in the east (Figure 4a). Leaf *d* groups subbasins located in the upper course of the river and in the basin’s western part. The actual evapotranspiration threshold to split leaves *c* and *d* is 1,064 mm, value above the basin average (Figure 4c). For subbasins with actual evapotranspiration below the threshold, leaf *c*, the median of months in the severe drought category is below ten (Figure 8c). For subbasins with actual evapotranspiration above the threshold, leaf *d*, the median of months in the severe drought category is sixteen, one of the highest among the terminal groups (Figure 8d).

Leaves *e*, *f* and *g* cluster twenty-four, six and twelve subbasins, respectively. Subbasins are located in the river valley and the basin's western part. In these subbasins, precipitation was below the basin average (Figure 4a), and actual evapotranspiration was above the average (Figure 4c). The percolation threshold to split leaves *e* and *f* from leaf *g* is 111 mm, a value considerably below the basin average (Figure 4d). At the fifth level of split, the sediment yield threshold to split leaves *e* and *f* is 101 metric tons/ha, a value close to the average in the basin (Figure 4h). Figure 8e, *f* and *g* show that subbasins clustered in these leaves are prone to agricultural droughts. The median of months in the moderate drought category was above twenty months; the severe category was above ten months; and the three leaves exhibited months in the extreme drought category.

Leaves *h*, *i* and *j* cluster twenty-six, fifty-two and fifty-six subbasins, respectively. Subbasins are mainly located in the wetland surroundings, La Serranía (leaf *i*), and some outliers are located in the basin's north (leaves *h* and *j*). Percolation in leaves *h*, *i* and *j* was close to the basin average (Figure 4d). Actual evapotranspiration in terminal groups *h* and *i* was relatively close to the basin average (Figure 4c). The water yield threshold to split clusters *h* and *i* is 352 mm. Overall, subbasins clustered at leaves *h*, *i* and *j* presented low susceptibility to severe and extreme agricultural drought conditions. The median of months in the moderate drought category was slightly higher than ten; the median for months in the severe category was the lowest for the study area and showed no months in the extreme drought category (Figure 8h, *i*, *j*).

Leaves *k* and *l* cluster two and six subbasins, respectively. Subbasins are located towards the basin's north, and one outlier is observed in the subbasin east (leaf *l*). In these subbasins, percolation was lower than 271 mm, value relatively low compared to other basin areas (Figure 4d). In leaf *k*, the curve number was lower than sixty-seven, while in leaf *l*, it was higher. In leaf *k*, the median of months for the moderate category is ten, and for the severe category, it is above 10. In leaf *l*, the median of months in the moderate category is above ten, and the subbasins experienced some months in severe drought. Leaves *k* and *l* show no months in the extreme drought category (Figure 8k and l).

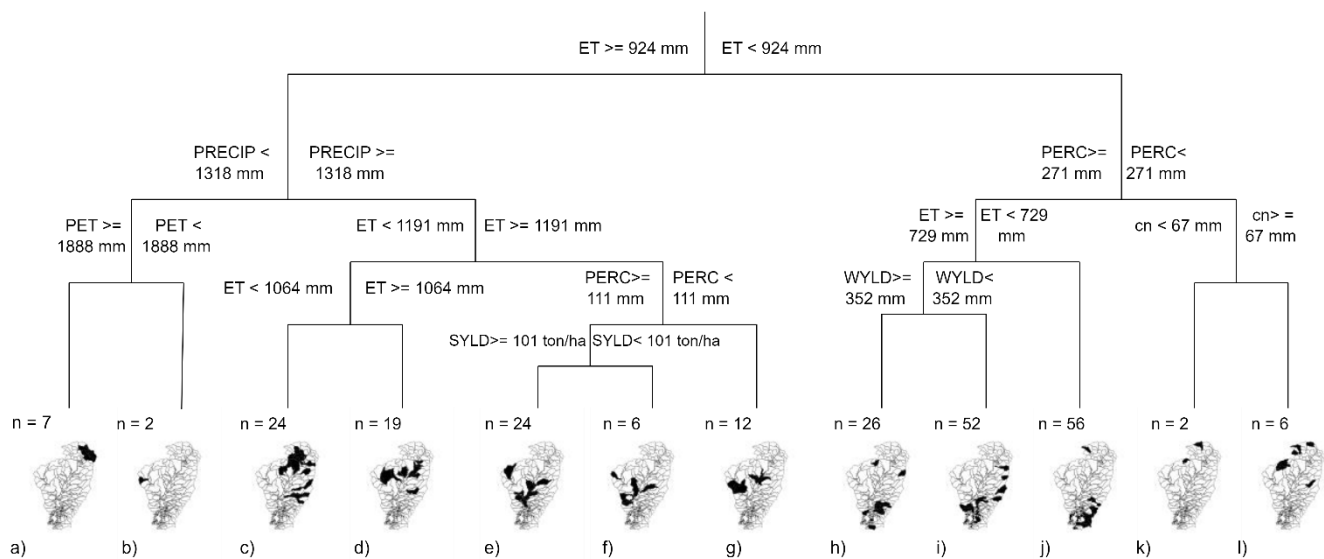

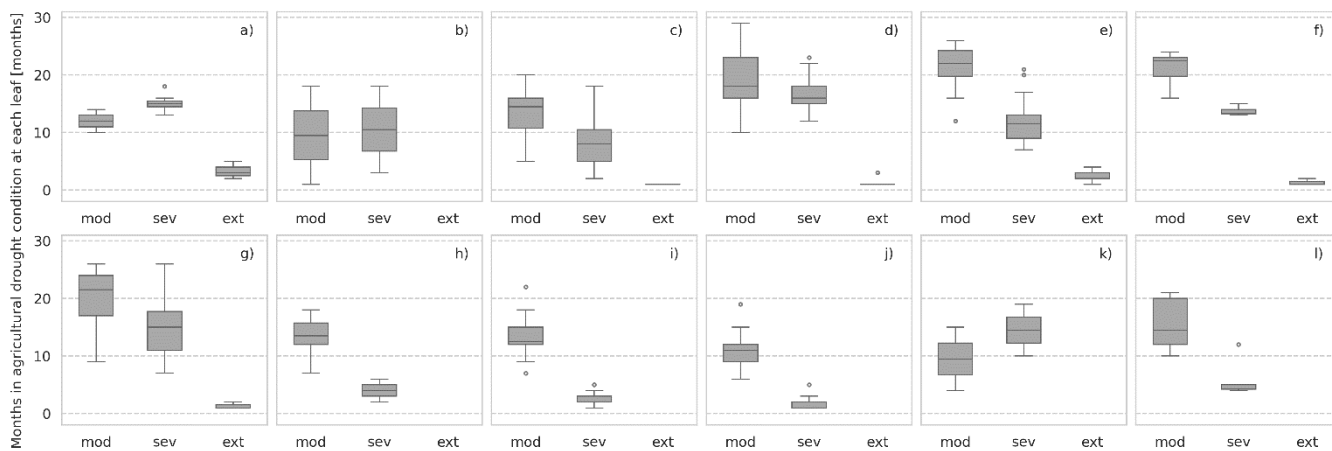

Figure 7 MVRT of hydroclimatic drivers of agricultural droughts at the Cesar River basin, and spatial distribution of the subbasins clustered at each leaf. Tree leaves are named from *a* to *l* and *n* indicates the number of subbasins clustered at each leaf.

415

Figure 8 Number of months in agricultural drought categories (moderate, severe, extreme) at each leaf. Tree leaves are named from *a* to *l*.

3.5.2 Drivers of hydrological drought

Figure 9 presents the hydrological drought MVRT, the number of subbasins clustered at each terminal group (variable “*n*”) and the spatial distribution of these subbasins. The tree consists of four levels of split and eight leaves. The minimum value of the cross-validation error ($CVRE = 0.67$) was used to select the tree size. The relative error of the MVRT was 0.52, and the EV was 0.48. Figure 10 presents the tree’s numerical output: namely, the number of months for each drought category. This information allowed us to identify the clusters of subbasins prone to hydrological droughts.

The MVRT demonstrated that precipitation was a primary driver of hydrological drought; it appeared two times at different levels of split. The subbasins were separated at the first split level according to precipitation (1632 mm). At the second split level, precipitation (1398 mm) was used as the left branch of the tree, and water yield was used as the right branch (29 mm). The left branch was then further divided according to percolation (153 mm) at the third level and according to curve number (51) at the fourth level. At the third level, the right branch was split according to evapotranspiration (833 mm) and surface runoff (0.5 mm). The MVRT terminal groups were then examined in detail.

430

Leaf *a* clusters twenty-eight subbasins in the upper basin and one outlier located in the western part of the subbasin (Figure 9a). In these subbasins, precipitation was considerably below the basin average (Figure 4a). Figure 10a shows that the subbasins in this terminal group repeatedly experienced moderate, severe and extreme hydrological drought.

435 Leaves *b* and *c* cluster thirty-seven and thirteen subbasins, respectively. Subbasins clustered at leaf *b* are relatively distant; most are towards the eastern part of the basin, and the rest are in the north and west of the basin. Subbasins in leaf *c* are located in the river's middle course towards the western part of the basin and some outliers in the north. Precipitation and percolation were slightly above the basin average in subbasins clustered at leaves *b* and *c* (Figure 4a and d). The curve number threshold to split leaves *c* and *d* is 51. Subbasins with a curve number above the threshold, leaf *b*, experience months in extreme drought and present one of the highest median of months for severe drought (Figure 10b). For subbasins with curve number below the threshold, leaf *c*, the median of months at moderate drought is almost 20 and experience months at severe and extreme category (Figure 10c).

445 Leaf *d* clusters twenty-nine subbasins in the river's middle course and the basin's eastern part. Figure 10d indicates that in this terminal group, the subbasins experienced fewer months in the severe and extreme drought categories than the other clusters in the tree's left branch; however, subbasins experienced one of the highest median of months at moderate drought.

In leaves *e* ($n = 72$) and *f* ($n = 18$), precipitation and water yield exceeded the basin average (Figure 4a and g). The actual evapotranspiration threshold to split leaves *e* and *f* is 833 mm, value below the basin average (Figure 4c). Both terminal groups describe moderate exposure to hydrological drought. At leaf *e*, the median of months in the severe and extreme drought categories is below ten, while the median of months in the moderate drought category is twenty (Figure 10e). The hydrological drought exposure of the subbasins clustered at leaf *f* is also mild. In these subbasins, actual evapotranspiration is above the threshold and close to the basin average. These subbasins present the lowest median of months for all drought categories (Figure 10f). Notably, the Zapatos marsh and upstream subbasins are clustered in this terminal group (Figure 9f).

455

Leaves *g* and *h* cluster seventy-one and forty subbasins, respectively. Subbasins clustered at these leaves are located upstream of the Zapatos marsh. The surface runoff threshold to split the leaves *g* and *h* is 0.5 mm. Figure 10g shows that the subbasins

grouped at leaf *g* present the low susceptibility to hydrological drought. The median of months for all categories is the lowest in the basin. In leaf *h*, the surface runoff was lower than 0.5 mm. In these subbasins, the medians of months in the severe and extreme categories are relatively low, while the median of months in the moderate category is eighteen (Figure 10h).

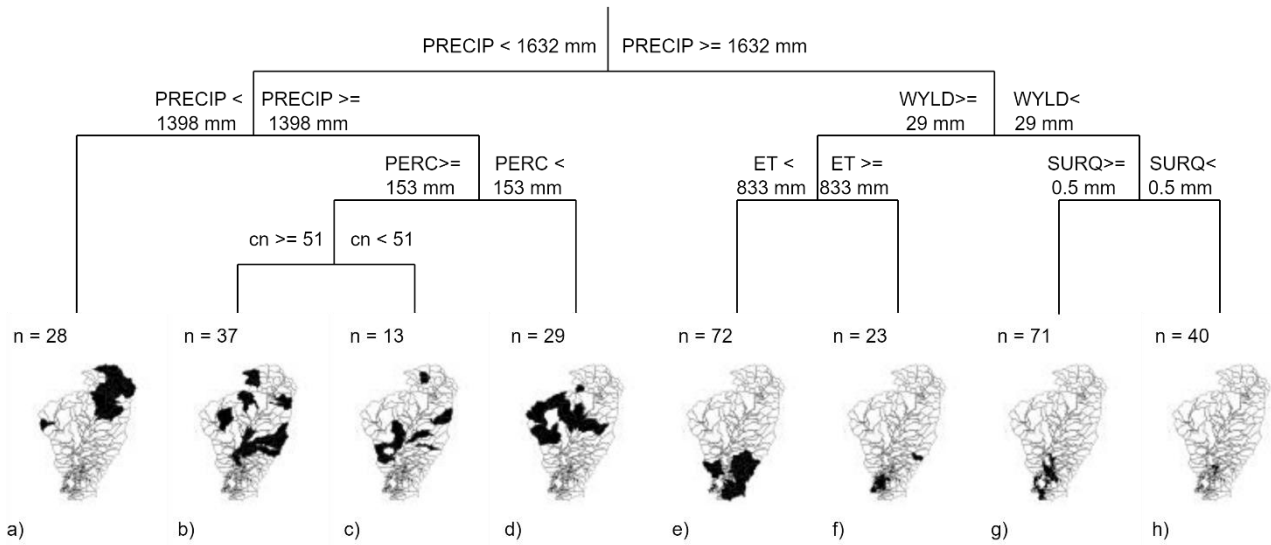

Figure 9 MVRT of hydroclimatic drivers of hydrological drought at the Cesar River basin, and spatial distribution of the subbasins clustered at each leaf. Tree leaves are named from *a* to *h* and *n* indicates the number of subbasins clustered at each leaf.

4. Discussion

4.1 Hydroclimatic drivers of agricultural drought

470 The left branch of the MVRT clusters the subbasins susceptible to severe agricultural drought (Figure 8a, d, e, f and g).
Conversely, the right branch of the MVRT clusters the subbasins experiencing moderate agricultural drought severity. The
subbasins in leaves *h*, *i* and *j* predominately experienced months in the moderate drought category (Figure 8h, i, and j).

Interestingly, agricultural drought severity in leaves *a*, *e*, *f* and *g* was comparable but governed by different parameters. For
475 instance, leaf *a* presented the highest median of months for severe and extreme agricultural drought (Figure 8a). The drought
drivers in this terminal group, namely precipitation and potential evapotranspiration, indicate that agricultural drought results
from an imbalance between the soil moisture supply (i.e. precipitation relatively close to the minimum value at the basin) and
soil moisture demand (i.e. moderately high potential evapotranspiration). Leaves *b*, *c*, and *d* corroborate the significant
influence of evapotranspiration on agricultural drought severity. A comparison of clusters *a* and *b*, and *c* and *d* indicates that
480 the leaves with higher evapotranspiration are more prone to experience severe drought. It is interesting to notice that in clusters
c and *d*, the actual evapotranspiration threshold causes a notable difference in drought severity. While the leaf *c*, clustering
subbasins with actual evapotranspiration below 1064 mm, presents the lowest median of months at severe category at the left
branch of the tree, leaf *d* shows the highest median of months at the same category in the tree.

485 This finding aligns well with studies demonstrating that potential evapotranspiration considerably enhances the severity of
agricultural droughts in water-limited areas (Ding et al., 2021; Manning et al., 2018; Teuling et al., 2013). According to such
studies, potential evapotranspiration influence on agricultural drought severity may be explained by the significant increase in
net radiation during droughts, as the lack of rainfall usually concurs with decreased cloud cover.

490 In contrast, the MVRT outcomes suggest that a lack of precipitation is not a primary driver of agricultural drought in the
subbasins clustered at leaves *e*, *f* and *g*. Particularly, leaf *e* grouped the subbasins that experienced the most severe agricultural
drought in the analysis period. The median of months in the moderate drought category was above twenty; the severe category
was above ten; and subbasin experienced months in extreme category (Figure 8e). The observed evapotranspiration and
percolation thresholds might indicate poor precipitation partitioning and a disturbed water regime that favours water lost by
495 runoff and evapotranspiration. Furthermore, the sediment yield threshold (notably above the median) may be linked to poor
soil structure, thus compromising soil water retention capacity and enhancing drought severity.

The results from leaf *f* show that a lower sediment yield slightly reduces the severity of extreme droughts (Figure 8f), as
compared to the results from leaf *e*. This is in good agreement with the findings by Masroor et al. (2022), Trnka et al. (2016)
500 and Santra et al. (2020), who found that soil erosion enhances the characteristics of agricultural drought. Further, our results

are consistent with previous studies that indicate the incidence of droughts is not only caused by extreme weather events but also by the inefficient soil–water management associated with land and soil degradation (Cornelis et al., 2019; Wildemeersch et al., 2015).

505 The right branch of the tree provides valuable information on the hydroclimatic parameters that reduce the severity of agricultural droughts. Moderate drought susceptibility for leaves *h*, *i* and *j* is linked to relatively low evapotranspiration thresholds; accordingly, it may be asserted that evapotranspiration controlling measures (e.g. surface cover, crop rotation, agroforestry, intercropping) are relevant interventions for building resistance to agricultural drought. At terminal groups *h* and *i*, water yield was found to influence the severity of agricultural drought. Notably, the subbasins at leaf *i* were slightly more
510 resistant to drought (Figure 8i); this indicates that measures aimed at increasing the subbasins' water storage capacity (e.g. rainwater and floodwater harvesting techniques) are suitable interventions to reduce the severity of agricultural drought.

Some of the subbasins grouped at leaf *i* showed high exposure to hydrological drought (Figure 10b and c). Contrasting exposure to agricultural and hydrological droughts suggest that the water retention capacity in these subbasins reduces the severity of
515 agricultural drought events but limits the contribution of surface runoff, lateral flow and groundwater to the streamflow, thus exacerbates the water deficit and hydrological drought severity. Therefore, drought management interventions require the prior assessment of the potential effects on both types of droughts.

4.2 Hydroclimatic drivers of hydrological droughts

The subbasins clustered on the left branch of the tree were prone to hydrological drought (Figure 10a, b, c, d). Leaf *a* presented
520 the highest median for months in the severe and extreme hydrological categories. The analysis results confirmed that precipitation deficits caused the severe hydrological drought conditions in the upper part of the basin.

Conversely, the MVRT also showed that in terminal groups *b*, *c* and *d*, hydrological drought severity was linked to the inefficient partition of precipitation. Selected drivers (precipitation, percolation and curve number representing land use) are
525 widely recognised as predominant drivers of hydrological droughts (Iglesias et al., 2018; Stoelzle et al., 2014; van Lanen et al., 2013; van Loon, 2015). The difference observed between the precipitation and percolation thresholds suggests that a large part of rainwater was lost either by evapotranspiration or surface runoff (or other water abstractions, e.g., human consumption, agriculture). Low percolation values limited the groundwater contribution to the streamflow, enhancing the streamflow deficit during drought periods.

530

Interestingly, the curve number was selected as a driver of hydrological drought for leaves *b* and *c* (Figure 9b and c). The subbasins in leaf *b* presented higher curve numbers than those in leaf *c* and higher exposure to hydrological drought. High curve number values are commonly the result of anthropogenic changes in land cover, which modifies evapotranspiration and

the division of precipitation into evapotranspiration and streamflow. The present selection of the curve number at the third
535 level of split is consistent with previous studies, which established that hydroclimatic parameters and human activities
influence hydrological droughts; however, the influence of both drivers is uneven. Results indicate that hydroclimatic
parameters are more influential (Jehanzaib et al., 2020; Saidi et al., 2018).

The right branch of the MVRT grouped subbasins with moderate and intermediate exposure to hydrological drought. The
540 hydroclimatic parameters and the thresholds used to define leaves e and f (precipitation, water yield and evapotranspiration)
demonstrate that in these subbasins, precipitation values compensated for the water abstraction by evapotranspiration. When
we compare the severity of the hydrological droughts observed in leaves e and f , we find that lower values of evapotranspiration
reduce exposure to severe and extreme hydrological drought but increase the incidence of moderate hydrological drought.

545 The subbasins in terminal group g experienced the lowest median number of months for all hydrological drought categories
(Figure 10g). The selected drought drivers and thresholds indicate that surface runoff reaches the streamflow, and the amount
of water that leaves the subbasins and contributes to the discharge downstream is limited (low water yield). Both characteristics
reduced hydrological drought severity. It can be explained by the subbasins' proximity to the marsh (which acted as a natural
control), the low slope in the area (which reduced streamflow velocity) and the presence of water bodies (which collected and
550 stored runoff during the rainy season) may have enhanced the water retention capacity in these areas. The observed moderate
exposure of these subbasins fits the results of earlier analyses, which found that wetlands exert significant impacts on the
alleviation of hydrological drought severity when direct evaporation from the water body does not significantly reduce water
storage (Wu et al., 2023). Thus, the present findings indicate that the water storage capacity of the Zapatos marsh can
compensate for the increased evaporation that occurs during drought events, thereby alleviating hydrological drought severity
555 upstream.

The hydrological drought conditions in the subbasins clustered at leaf h were mild, despite water yield values below 29 mm
(Figure 10h). Negligible surface runoff values indicated that in leaf h , rainfall is stored in the soil profile, lost by
evapotranspiration or percolates in an area of minimal baseflow contribution to streamflow. This limits the amount of water
560 reaching the streamflow and enhances the severity of hydrological droughts, compared to leaf g .

4.3 Comparison of the hydroclimatic parameters influencing the severity of agricultural and hydrological droughts

Crucial similarities and differences emerge from contrasting the parameters influencing the severity of droughts and the spatial
distribution of the subbasins experiencing severe and mild drought conditions. MVRTs indicate that severe agricultural and
hydrological drought conditions occurred in the upper and middle course of the river. Nevertheless, the severe droughts were
565 influenced by different hydroclimatic factors. Severe agricultural drought in the headwater was driven by the interaction
between precipitation shortfalls and high potential evapotranspiration (Figure 7a). Conversely, severe hydrological drought

condition was solely driven by limited precipitation. It is worth highlighting that the severe hydrological situation extends from the headwater to subbasins in the middle course (Figure 9a).

570 Downstream, in subbasins located in the middle course, the agricultural and hydrological drought situation was also severe. In this area, droughts' severity was linked to inadequate rainfall partitioning and an unbalanced water cycle that favours water loss through evapotranspiration and low percolation values (Figure 7d, e, f and g, and Figure 9b, c and d). Significantly, agricultural and hydrological droughts in these leaves were more severe than in leaves experiencing precipitation deficits (Figure 7a and Figure 9a). Results also suggest that poor soil structure enhanced severe agricultural drought conditions (Figure 575 7e), and high curve numbers seem to increase hydrological drought severity (Figure 9b).

MVRTs also showed subbasins experiencing mild agricultural and hydrological drought severity. Overall, these subbasins were located in the southern part of the basin. However, for agricultural drought, a few cases were observed in the north of the basin (Figure 7h, i and j). Subbasins presenting mild hydrological drought severity allocate upstream of the Zapatos marsh (Figure 9g). Moderate agricultural drought severity was linked to low evapotranspiration losses and basin capacity to retain 580 water in the soil profile, improving percolation (Figure 7j). In turn, moderate hydrological drought severity related to the subbasins' proximity to the marsh (which acted as a natural control reducing the water yield) and surface runoff contributions to the streamflow (Figure 9g). Remarkably, some of these subbasins also showed mild agricultural drought conditions (Figure 7i).

585 **4.4 Accuracy of the MVRTs**

The high EV (0.81) value is an indication of the good explanatory power of the tree built for agricultural drought. This confirms that the selected explanatory variables significantly influence the severity of agricultural drought. Nevertheless, two potential disadvantages of the tree are identified. First, clusters *h* and *i* are very similar. Drought severity is alike in these leaves, and the parameters influencing droughts are the same. This suggests that these two clusters can be merged into one cluster. Second, 590 leaves *b* and *k* cluster only two subbasins. Accordingly, the distribution presented in the boxplots must be interpreted cautiously. Neither of these disadvantages compromises the study's main findings; however, further analysis is recommended to determine the size of the tree (number of clusters) that better fits the assessment of the hydroclimatic drivers of droughts.

Conversely, the explanatory power of the tree built for hydrological drought is not very high (EV = 0.48). This may be related 595 to the inaccurate representation of groundwater contribution to the streamflow. Streams depend significantly on groundwater during droughts to maintain flow; nevertheless, groundwater contribution to the streamflow was not included as a key drought driver in the MVRT, although it was in the list of explanatory variables. It is possible that the model's simplifications for the simulation of groundwater flow and storage did not adequately represent the groundwater contribution to the streamflow (Molina-Navarro et al., 2019). The lack of adequate information about this relevant factor hydrological drought may have

600 compromised the MVRT's accuracy. Unexplained variability may also link to factors that influence hydrological drought but were not considered in the dataset of explanatory variables (e.g. abstractions such as water for irrigation, industry or human consumption).

5. Conclusions

605 In this study a machine learning technique, namely multi-variate regression tree, was applied. The main aim was to build an 'explanatory AI' model to explicitly identify relationships between a subbasin's hydroclimatic characteristics (i.e. explanatory variables) and the severity categories of agricultural and hydrological drought (i.e. response variables). The results show that the machine learning technique identifies drought severity's primary drivers and critical thresholds reasonably well. The MVRT also identifies parameters which can contribute to reducing agricultural and hydrological drought severity.

610 The outcomes of the MVRT provide valuable information on the hydroclimatic parameters influencing the drought-generating process in the Cesar River basin. MVRTs indicate that severe agricultural and hydrological drought conditions observed in the upper and middle course of the river are influenced by different hydroclimatic factors. The interaction between precipitation shortfalls and high potential evapotranspiration drives severe agricultural drought in the headwater. Conversely, severe hydrological drought condition is mostly caused by limited precipitation. In subbasins in the middle course, droughts' severity
615 is linked to inadequate rainfall partitioning and an unbalanced water cycle favouring water loss through evapotranspiration and low percolation values. Notably, results suggest that poor soil structure enhances severe agricultural drought conditions, and high curve numbers seem to increase hydrological drought severity. In the southern region, subbasins experience moderate agricultural and hydrological drought severity. Mild agricultural drought is linked to low evapotranspiration losses and basin capacity to retain water in the soil profile, improving percolation. In turn, moderate hydrological drought severity relates to
620 the subbasins' proximity to the marsh (which acted as a natural control reducing the water yield) and surface runoff contributions to the streamflow. The outcomes of this study also demonstrate that the combined effect of parameters with low impact can trigger a drought situation as severe as the one produced by one or two of the most influential parameters. It is worth mentioning that the study outcomes indicate that the slope and the soil type do not influence the severity of agricultural and hydrological droughts in the Cesar River Basin.

625

It can also be concluded that the MVRT (and other machine learning techniques that generate 'explainable AI' models based on progressive tree-like data partitioning and simplified models in leaves) is a relevant tool for defining drought management strategies. The tool helps to identify drought-prone areas and design management strategies that contribute to maintaining the hydrological parameters influencing droughts above (or below) the thresholds that trigger severe and extreme drought
630 conditions.

This study is not without limitations. First, we used a simplified approach to modelling a complex phenomenon using SWAT software (e.g. representing the groundwater components that impact hydrological drought conditions). Second, only a single ML technique was employed to build explainable models. Further extensions of this research may address these limitations. For example, candidate ML techniques could include M5 model trees (rather than regression trees), which have shown their effectiveness in solving water-related problems (see Solomatine & Dulal, 2004; Solomatine & Xue, 2004). These result in linear models in tree leaves rather than constants like in regression trees. Additionally, there is still a need to better represent anthropogenic interventions (and other relevant parameters influencing droughts) in the set of explanatory variables, e.g. abstractions such as water for irrigation, industry or human consumption, groundwater pumping.

640 The issue of combining human and artificial intelligence (and knowledge of physics with machine learning) is currently a point of great interest (see Jiang et al., (2020) on ‘physics-aware deep learning models’, Moreido et al., (2021) and Bertels et al, (2023), on the role of experts in constraining machine-learning hydrological models). However, the mentioned approaches incorporate the physical knowledge into ML models directly, and the resulting models are still seen by domain experts as “black boxes”. This study can be seen as the one that contributes to developing and testing tools to better incorporate

645 ‘explanatory’ ML, leading to models that can be overviewed and analysed by experts, and hence have better potential for inclusion into existing modelling and management practices.
