Abstract.

There is a scientific consensus that the Mediterranean Region (MedR) is warming and as the temperature continues to rise, droughts and heat waves are becoming more frequent, severe, and widespread. Given the detrimental effects of droughts, it is crucial to accelerate the development of forecasting and early warning systems to minimize their negative impact. This paper reviews the current state of drought modeling and prediction applied in the MedR, including statistical, dynamical, and hybrid statistical-dynamical models. By considering the multifaceted nature of droughts, the study encompasses meteorological, agricultural, and hydrological drought forms and spans a variety of forecast scales, from weekly to annual timelines. Our objective is to pinpoint the knowledge gaps in literature and to propose potential research trajectories to improve the prediction of droughts in this region. The review finds that while each method has its unique strengths and limitations, hybrid statistical-dynamical models appear to hold the most promising potential for skillful prediction with seasonal to annual lead times. However, the application of these methods is still challenging due to the lack of high-quality observational data and the limited computational resources. Finally, the paper concludes by discussing the importance of using a combination of sophisticated methods such as data assimilation techniques, machine learning models, and copula models and integrating data from different sources (e.g., remote sensing data, in-situ measurements, and reanalysis) to improve the accuracy and efficiency of drought forecasting.

Key Words: drought, forecasting, data assimilation, machine learning, Mediterranean, review

1 Introduction

Drought is a recurrent phenomenon in the Mediterranean Region (MedR). Throughout time, adaptation to this kind of climate event has been an important issue for the development of many countries in the region. Yet, with the disruptive accelerated impact of global warming, already reflected in more regular and intense droughts around the Mediterranean in the last few decades, building resilience to extreme weather conditions remains a true challenge (Satour et al., 2021). For these reasons among others, the region is often described as a hotspot for climate change (Tuel and Eltahir, 2020). The Intergovernmental Panel on Climate Change (IPCC) pointed out in the Sixth Assessment Report (AR6) that global warming has been more rapid in the Mediterranean than in the rest of the world (IPCC, 2021). This report projected an increase in the frequency and/or severity of agricultural and ecological droughts across the Mediterranean and Western Africa (IPCC, 2021). A global increase of 2 °C is thought to correspond to a 3 °C increase in the daily maximum temperature in the MedR (Seneviratne et al., 2016;

38 Vogel et al., 2021). If this increase in temperature continues at the same pace, MedR is susceptible to experience
39 fearful desertification by the end of the 21st century, driving an increase in aridity (Carvalho et al., 2022).

40 This will surely lead to irreversible biodiversity loss and diminish the capability of semi-arid Mediterranean
41 ecosystems to function as effective carbon sinks in the future (Valentini et al., 2000; Briassoulis, 2017; Zeng et
42 al., 2021). These conditions exacerbate water stress, which, in turn, enhances the probability of wildfire (Turco et
43 al., 2017a). A phenomenon already witnessed these two last summers (2021 and 2022) in several Mediterranean
44 countries (Turkey, Greece, Italy, Algeria, and Morocco), displacing thousands, killing hundreds, and causing
45 irreparable damage (Rodrigues et al., 2023; Yilmaz et al., 2023; Eberle and Higuera Roa, 2022).

46 The Mediterranean Sea (MEDS), lying between Africa, Europe, and Asia, serves as a substantial source of
47 moisture and heat, affecting atmospheric circulation and weather patterns (Mariotti et al., 2008). Its narrow
48 connection to the Atlantic Ocean via the 14 km wide Strait of Gibraltar and the surrounding varied topography
49 (Fig. 1), with vegetated areas to the north and desert areas to the south and east, contribute to the region's complex
50 climate dynamics (Michaelides et al., 2018).

51 The MedR is characterized by a mid-latitude temperate climate with mild rainy winters and hot, dry summers
52 (Lionello et al., 2023). Notably, this area is positioned in a transitional band between the midlatitude and
53 subtropical regions, which makes climate modeling for this region quite challenging (Planton et al., 2012). The
54 Mediterranean climate exhibits a strong spatial gradient in precipitation, with generally decreasing precipitation
55 values towards the south and hardly any precipitation during the summer (Lionello, 2012). Such conditions pose
56 challenges in climate modeling and can lead to severe impacts on water supply and agriculture, especially in
57 regions relying on rain-fed agriculture (Tramblay et al., 2020).

58 Water availability is unevenly distributed among the Mediterranean countries with 72% in temperate countries of
59 the North, against 5% in the South, and 23% in the East (Milano et al., 2013). Accordingly, several countries such
60 as Algeria, Morocco, Egypt, Libya, Malta, and some countries of southern Europe such as Portugal and Spain are
61 experiencing a structural water shortage that is likely to increase with the expected population growth (Sanchis-
62 Ibor et al., 2020). This situation is further aggravated when multi-annual droughts hit the region. In this challenging
63 context, drought forecasting that provides seasonal to annual lead times becomes critically important for proactive
64 agricultural and water resources management.

65 Growing concern about the drought phenomenon in the last decades has spurred the development of improved
66 systems that predict the full cycle of drought (onset, duration, severity, and recovery) via a large number of indices
67 and models. Common approaches to predicting drought can be subdivided into two categories of models: statistical
68 models and dynamical models. Statistical models, also named data-driven models, rely on the estimated
69 correlations between several predictors (large-scale climate variables) and predictands (local climate variables
70 represented by historical observations). The climatology-based or persistence-based models, like the Ensemble
71 Streamflow Prediction (ESP) system, form an essential tool in this category, leveraging both historical and near
72 real-time data to generate a probabilistic forecast of future drought events (AghaKouchak, 2014a; Turco et al.,
73 2017b; Torres-Vázquez et al., 2023). Meanwhile, dynamical drought prediction relies on the use of Global Climate
74 Models (GCMs) to simulate the dynamical processes that govern hydroclimatic variability. Nevertheless, despite
75 the usefulness of these models in drought prediction and early warning systems, their forecast accuracy remains

76 limited for longer lead times (exceeding one month) (Wood et al., 2015). The post-processing and multi-model
77 ensemble techniques are usually used to improve prediction skills by avoiding systematic bias related to the coarse
78 resolution of GCMs (Han and Singh, 2020). Recently, drought prediction has also been tackled by the hybrid
79 statistical-dynamical models which combine the two approaches mentioned above. These models constitute a
80 promising tool for long lead-time drought forecasting (Ribeiro and Pires, 2016).

81 Despite the efforts made to predict drought phenomena, it remains largely little understood due to its multiple
82 causing mechanisms and contributing factors (Kiem et al., 2016; Hao et al., 2018). The complexity and variability
83 depicted by many physical mechanisms such as Sea Surface Temperature (SST), North Atlantic Oscillation
84 (NAO), El Niño—Southern Oscillation (ENSO), Mediterranean Oscillation (MO), and land-atmosphere feedback
85 are also responsible for the low performance of drought monitoring and forecasting (Ayugi et al., 2022).
86 Understanding the synoptic conditions leading to the drought phenomenon becomes increasingly important given
87 the upward trend in temperature in the MedR. Further investigations to assimilate how large-scale teleconnections
88 affect local weather and climate anomalies, as well as how these later feedback into the larger context, are much
89 needed in this context.

90 To address these questions, numerous review papers have sought to consolidate the scientific advances in drought
91 prediction from different regions of the world (e.g., Mishra and Singh, 2011; Hao et al., 2018; Fung et al., 2019;
92 Han and Singh, 2020). While these studies provided a comprehensive overview of drought prediction at a global
93 scale, our paper offers an in-depth analysis of drought prediction methodologies specifically applied to the
94 Mediterranean context. This is achieved through an examination of the applicability, strengths, and limitations of
95 statistical, dynamical, and hybrid statistical-dynamical models, in line with the regional specifics of the MedR.
96 This specificity is vital given that drought, as a phenomenon, is highly region dependent. The unique
97 meteorological conditions of the MedR necessitate dedicated studies, as solutions developed for other regions may
98 not be applicable or effective here.

99 Trambly et al. (2020) emphasized the urgent need for drought modeling and forecasting methods designed for the
100 Mediterranean context, particularly as climate change continues to exacerbate drought conditions in this region.
101 Building on this, our work not only emphasizes the complexities of drought assessment but also conducts a critical
102 review of recent drought forecasting methodologies applied specifically to the MedR. In addition to shedding light
103 on the merits and limitations of these methods, our investigation also helps identify underexplored areas that
104 warrant further research. Detecting these gaps is a crucial aspect of our work, as it directs future research towards
105 these relatively unexplored realms of drought prediction.

106 The structure of this paper is as follows: Section 2 highlights the difficulty related to the definition of drought from
107 different perspectives. The causes of drought in MedR are provided in section 3. Sections 4, 5, and 6 present the
108 recent advances in drought prediction with statistical, dynamical, and hybrid statistical-dynamical models
109 respectively. Section 7 discusses the results found in this review, providing insights into the current state of drought
110 forecasting in the MedR and highlighting potential areas for improvement. The challenges in drought prediction
111 are reviewed with the prospects in section 8. Finally, the 9th section presents the conclusions of the whole paper.

112 **Figure 1 Topography of the Mediterranean Region (30°N - 46°N in latitude and 10°W - 40°E in longitude).**

113 **2 Drought Definitions, Classification, and Indices**

114 Drought is a compound phenomenon of creeping nature. Establishing an accurate prediction, well describing its
115 starting date and duration is extremely hard. The multidisciplinary and multiscale nature of drought renders the
116 understanding of this phenomenon very challenging (AghaKouchak et al., 2021). As a matter of fact, literature
117 gives numerous definitions for drought.

118 In the eighties, Wilhite and Glantz (1985) found more than 150 published definitions of drought that can be
119 categorized into four broad groups: meteorological, agricultural, hydrological, and socioeconomical. This
120 classification based on both physical and socioeconomic factors is still adopted today. As this classification is
121 human-centered, some recent works emphasized the need to consider the ecological drought as well, which creates
122 multiple stresses in natural ecosystems, see for example Crausbay et al. (2017), Vicente-Serrano et al. (2020),
123 Bradford et al. (2020) and Zhang et al. (2022). Since the aim of this study is to review forecasting drought methods,
124 we will focus only on the first three categories that provide direct methods to quantify drought as a physical
125 phenomenon.

126 In an attempt to associate a mathematical definition with each drought type, several drought indices have emerged.
127 These indices are typically based upon some hydroclimatic variables or parameters (indicators) such as
128 temperature, precipitation, soil moisture, streamflow, and snowpack to describe three major characteristics of the
129 drought event: severity, duration, and frequency. However, the lack of a universal definition of drought is also
130 apparent in the huge variety of indices (more than 100) that have been developed for drought prediction (Lloyd-
131 Hughes, 2014). Unfortunately, this plethora of indices creates more confusion than clarity (Lloyd-Hughes, 2014)
132 and makes the choice of the most suitable indices a difficult task.

133 **2.1. Meteorological Drought**

134 The World Meteorological Organization (WMO) characterizes meteorological drought as “a prolonged absence
135 or marked deficiency of precipitation”. Similarly, the IPCC defines meteorological drought as “a period of
136 abnormally dry weather in a region over an extended period”. The threshold to distinguish between a dry or wet
137 period often depends on the average rainfall typical for the specific area under study. This gives rise to a variety
138 of meteorological definitions, each tailored to the distinct conditions of diverse regions or countries (Isendahl,
139 2006). Regarding the MedR, creating a single encompassing definition of meteorological drought is particularly
140 challenging. This complexity stems from the diverse climate conditions across the region, particularly the
141 pronounced variability between eastern and western meteorological conditions that contribute to drought.

142 The Standardized Precipitation Index (SPI) (McKee et al., 1993) and the Standardized Precipitation
143 Evapotranspiration Index (SPEI) (Vicente-Serrano et al., 2010a) are two of the most prevalent indicators used to
144 describe meteorological drought. They owe their popularity to the recommendation of the WMO (Svoboda et al.,
145 2012). The SPI has been extensively used in previous studies for its ease of computation, its probabilistic nature,
146 and its ability to detect drought at multiple time scales (Madadgar and Moradkhani, 2013; Chen et al., 2013; Li et
147 al., 2020; Mesbahzadeh et al., 2020; Das et al., 2020). By fitting a probability distribution to observed precipitation
148 data, the SPI is calculated and subsequently transformed into a standard normal distribution with a mean of 0 and
149 a standard deviation of 1 (Livada and Assimakopoulos, 2007). Consequently, SPI values can be compared across
150 various regions and timeframes (e.g., 1, 3, 6, 12, or 24 months). This multiscale nature of SPI enables it to capture
151 diverse aspects of drought depending on the selected time scale. The shorter time scales (1-3 months) are suitable

152 for monitoring agricultural drought, while longer time scales (6-12 months or more) are better suited for evaluating
153 hydrological drought. However, it should be noted that the SPI considers only precipitation data and neglects the
154 variability of temperature and potential evapotranspiration (PET), ignoring the effect of warming on droughts.
155 Indeed, in relatively wet regions, precipitation deficit can constitute an important indicator for drought (Gamelin
156 et al., 2022). Yet, in midlatitude (or extratropic) regions such as the Mediterranean where the climatological
157 precipitation is modest or low, precipitation deficit may not be sufficient to measure extreme droughts.
158 Furthermore, knowing the upward trend in temperature and the influence of high atmospheric evaporative demand
159 (AED) in increasing severity of recent drought events in the MedR (Tramblay et al., 2020; Mathbout et al., 2021;
160 Bouabdelli et al., 2022), the choice of drought indices needs to prioritize those including these variables in their
161 formulation such as SPEI, or Palmer Drought Severity Index (PDSI) (Palmer, 1965) and Reconnaissance Drought
162 Index (RDI) (Tsakiris and Vangelis, 2005) to mention but a few.

163 The SPEI was developed by Vicente-Serrano et al. (2010a) using the climatic water balance concept of climatic
164 water supply and AED. It is based on precipitation and PET and has the advantage of combining the multi-scalar
165 character of the SPI with the ability to include the effects of temperature variability (Vicente-Serrano et al., 2010a).

166 A global assessment of drought indices conducted by Vicente-Serrano et al. (2012) found that SPEI provided a
167 superior capability in capturing drought impacts, particularly during the crucial summer season. Bouabdelli et al.
168 (2022) used SPI and SPEI indices and copula theory to study the impact of temperature on agricultural drought
169 characteristics under future climate scenarios over seven vast Algerian plains located in the MedR. The results of
170 this study confirmed that the frequency of drought events is much higher using SPI while their duration and severity
171 are more intense using SPEI. Russo et al. (2019) performed drought characterization in MedR using both SPEI and
172 SPI, considering the period 1980–2014. Their findings indicated that SPEI exhibits a stronger correlation with
173 drought conditions over a 3-month time scale, while SPI shows a better correlation for a 9-month duration. This
174 result highlights the ability of SPEI to capture the early shifts in the balance between evapotranspiration and
175 precipitation more efficiently than SPI (Russo et al., 2019).

176 Despite the utility of SPEI in drought characterization, it does have a noteworthy limitation. The effectiveness of
177 SPEI significantly relies on the method used for estimating PET such as the Penman-Monteith equation, the
178 Thornthwaite method, the Hargreaves method, and the Priestley-Taylor method among others. These estimation
179 methods can yield varying results, leading to inconsistencies in SPEI values. In essence, the sensitivity of SPEI to
180 the PET estimation method used could potentially affect the accuracy and reliability of the index in representing
181 drought conditions (Vicente-Serrano et al., 2010b; Stagge et al., 2014).

182 The PDSI has also been widely used to quantify the drought characteristics for a given location and time. It includes
183 precipitation, temperature, and soil moisture data to estimate water supply and demand and to reflect long-term
184 drought. But it has shown some inconsistencies when used at various locations (Wells et al., 2004). A self-
185 calibrating variant of this index (scPDSI) was proposed by Wells et al. (2004) to automatically calibrates the
186 behavior of the index by replacing empirical constants in its computation with dynamically estimated values to
187 account for the variability of precipitation and the climate characteristics between locations (Wells et al., 2004).
188 Ionita and Nagavciuc (2021) evaluated the drought characteristics at the European level over the period 1901–2019
189 using SPI, SPEI, and scPDSI. The results based on SPEI and scPDSI show that the increase in mean air temperature
190 and PET are making central Europe and the MedR dryer, whereas Northern Europe is getting wetter. While results

191 based on SPI using only precipitation data did not reveal this drought variability. This underscores the findings of
192 Vicente-Serrano et al. (2012), who emphasized the benefits of using more integrative indices like SPEI in
193 understanding and predicting drought variability more effectively.

194 The MedPDSI, which is an update of the PDSI formulation in terms of its soil water balance to consider real
195 evapotranspiration (based on reanalysis data instead of PET) in the MedR, has allowed an earlier identification of
196 longer and more severe droughts (Paulo et al., 2012). Paulo et al. (2012) compared SPI, SPEI, PDSI, and MedPDSI
197 in detecting drought characteristics in Portugal for the period 1941 to 2006. They concluded that PDSI and
198 MedPDSI are likely to identify better the supply-demand dynamics and that they may be of great interest for
199 drought warning applications, aiming namely at agriculture (Paulo et al., 2012).

200 **2.2. Agricultural Drought**

201 Agriculture is very sensitive to climate variation especially extreme weather. Due to its dependency on water
202 availability, this sector is strongly impacted by drought events. In the Mediterranean Basin, agricultural practices
203 span both rain-fed and irrigated systems. Rain-fed agriculture is prevalent, particularly for crops such as wheat and
204 barley, while crops like olives and citrus fruits, such as oranges, often utilize controlled irrigation systems to
205 supplement natural precipitation (Rodrigo-Comino et al., 2021). Regardless of the system employed, if
206 meteorological drought lasts for a prolonged period, it can lead to a reduction in soil moisture to such a level that
207 it harmfully affects crop production, especially during the active plant growth season (Wilhite and Glantz, 1985;
208 Mishra and Singh, 2010). At this stage the agricultural drought sets in.

209 Therefore, in addition to meteorological factors, the agricultural drought definition is also related to the retention
210 capacity of soil in the crop growth season (Kuśmierk-Tomaszewska and Żarski, 2021) which depends on crop
211 types, soil characteristics, and soil management. All these indicators can be employed to develop relevant
212 agricultural drought indices. Among them, we cite Crop Moisture Index (CMI) (Palmer, 1968); Soil Moisture
213 Deficit Index (SMDI); Evapotranspiration Deficit Index (ETDI) (Narasimhan and Srinivasan, 2005); Normalized
214 Soil Moisture index (NSMI) (Dutra et al., 2008) and Empirical Standardized Soil Moisture Index (SSMI) (Carrão
215 et al., 2016).

216 The formulation of these indices integrates soil moisture data, leveraging a variety of assessment techniques, each
217 with unique advantages. These include in-situ soil moisture probes, cosmic-ray neutron probes, and physically
218 driven models such as the ISBA land surface model (Tramblay et al., 2019). Each of these techniques has distinct
219 advantages and is suitable for different application contexts (Miralles et al., 2010; Martens et al., 2017). However,
220 when faced with the scarcity of observed soil moisture data, remote sensing comes to the forefront. It furnishes
221 extensive and frequent measurements of soil moisture characteristics, effectively supplementing areas where
222 observed data falls short. Yet, it is crucial to be aware of the limitations of these tools. Despite its indispensable
223 role, remote sensing is constrained by factors such as coarse temporal and spatial resolution, limited penetration
224 depth, and incompatible governing hydrologic principles (Mohanty et al., 2017; Gruber and Peng, 2022). As an
225 alternative, hydrological models have been commonly used to simulate and calibrate this variable in the context
226 of agricultural drought forecasts (Hao et al., 2018). Mimeau et al., (2021) used a modeling framework to estimate
227 soil moisture sensitivity to changes in precipitation and temperature at 10 plots located in southern France. They

228 concluded that the current climate change scenarios may induce longer periods of depleted soil moisture content,
229 corresponding to agricultural drought conditions.

230 In general, when soil moisture in the root zone reaches a critical level, farmers resort to irrigation to save crops
231 (Kang et al., 2000). However, nowadays agriculture consumes approximately 85% of global fresh water for
232 irrigation (D'Odorico et al., 2019; Tatlhego et al., 2022), which is expected to increase in the years to come by
233 growing population, increasing food consumption, and rising temperatures that accelerate PET and promote
234 hydrological stress.

235 **2.3. Hydrological Drought**

236 Unlike agricultural drought which is mainly affected by the depletion of soil moisture after a dry period, a lack of
237 precipitation impacts many components of the hydrological system in a river basin or watershed (streams,
238 reservoirs, and lakes). These define water availability that can be used for commercial navigation, generation of
239 hydroelectric power, irrigation of farmlands, industry, and domestic activities for several months after the
240 deficiency in precipitation. Consequently, hydrological drought lags behind the occurrence of meteorological and
241 agricultural droughts. This lag time is a characteristic of the watershed, which is defined based on many physical
242 drivers such as evapotranspiration capacity, soil properties, vegetation types, snow accumulation/melt, local water
243 management such as dams' construction and control, water supply operation rules, and irrigation strategy (Van
244 Loon and Laaha, 2015).

245 A hydrological drought is generally proclaimed when the water levels in streamflow, reservoirs, lakes, aquifers,
246 and other water storage systems fall below a specific threshold. Therefore, the hydrological drought prediction
247 necessitates the analysis of climate variables such as precipitation and temperature and initial catchment conditions
248 (e.g., snow cover, and soil moisture) (Hao et al., 2018).

249 In the Mediterranean Basin, a common tendency for water levels to drop in shallow lakes and aquifers has
250 motivated many researchers to study the hydrological drought in this region: Greece (Myronidis et al., 2012);
251 Turkey (Akyuz et al., 2012); Tunisia (Hamdi et al., 2016); Lebanon (Al Sayah et al., 2021); Italy (Di Nunno et al.,
252 2021); Portugal (Mendes et al., 2022); Algeria (Bouabdelli et al., 2022); Syria (Mohammed et al., 2022). The most
253 common hydrological drought indices include Palmer Hydrologic Drought Index (PHDI) (Palmer, 1965), the
254 Streamflow drought index (SDI) (Nalbantis, 2008), and Standardized Runoff Index (SRI) (Shukla and Wood,
255 2008).

256 As part of the effort made by Palmer in the sixties, the PHDI has been developed by using the same two-layer soil
257 model as the PDSI, but it applies a stricter criterion for determining the ends of drought to account for long-term
258 drought events that reduce surface and groundwater supply. Vasiliades and Loukas (2009) tested the Palmer
259 indices in a Mediterranean basin (in Greece) they concluded that these indices were successful in the identification
260 of drought severity of historical events, but they were unable to identify drought duration.

261 The SRI is an index that uses the same computational principles as SPI but uses monthly mean streamflow rather
262 than precipitation only to account for the hydrologic process that determines seasonal lags in the influence of
263 climate on streamflow (Shukla and Wood, 2008). Shukla and Wood (2008) compared the SRI and the SPI results
264 during drought events in a snowmelt region. They concluded that the SRI can be used as a complement to the SPI
265 for depicting hydrologic aspects of drought.

266 The SDI is also a simple index that uses the cumulative monthly streamflow volumes for a given hydrological year
267 to predict wet and dry periods and identify the severity of a hydrological drought (Nalbantis, 2008). Bouabdelli et
268 al. (2020) conducted a comparison study of the SPI and SDI, focusing on their characteristics across three
269 watersheds in northwestern Algeria. Their analysis revealed a substantial similarity between meteorological
270 drought events (as represented by SPI-12) and hydrological drought events (as indicated by SDI-6). This
271 correlation emphasizes the sensitive and responsive nature of these basins to dry conditions, further illustrated by
272 the swift transition from meteorological to hydrological drought events in the studied basins (Bouabdelli et al.,
273 2020).

274 The application of hydrological drought indices appears to be very valuable. However, the main challenge in
275 applying these indices lies in the requirement for a long-term series of climatic data. According to the WMO, up
276 to 30 years of continuous rainfall data may be necessary for accurate drought index calculations (WMO, 1994).
277 This condition is not always fulfilled which makes the rainfall-runoff transformation a difficult task (De Luca et
278 al., 2022). Modern hydrological models can offer a valuable counterpart to existing climate-based drought indices
279 by simulating hydrologic variables such as land surface runoff (Shukla and Wood, 2008).

280 **3 Overview of the physical mechanisms causing drought in the Mediterranean region**

281 It is difficult to determine the physical mechanisms causing droughts in the Mediterranean basin since the region
282 covers a complex landscape with high topographic and climatic heterogeneity, strong land-sea contrasts, and high
283 anthropic pressure (De Luca et al., 2022).

284 Considering the various forms of drought, meteorological droughts, characterized by a deficit in precipitation, are
285 commonly recognized as marking the onset of drought conditions. This initial stage is intrinsically linked to
286 precipitation predictability, which is driven by large-scale atmospheric motions such as Walker circulations and
287 Rossby waves, influenced by factors like SST anomalies, radiative forcing changes (both natural and
288 anthropogenic), and land surface interactions (Hao et al., 2018; Wood et al., 2015). However, due to the inherently
289 chaotic nature of atmospheric circulation, predictability, particularly for meteorological droughts, tends to
290 diminish beyond a one-month lead time. It is crucial to note that the reliability of these predictions can differ when
291 considering other drought types (such as agricultural or hydrological droughts) or altering the forecast scale, with
292 seasonal forecasts often displaying more reliability months in advance, while daily forecasts may face limitations
293 from around two weeks.

294 The discovery of teleconnections between SST anomalies and hydroclimatic phenomena constitutes a major
295 advance in drought forecasting and early warning (Wood et al., 2015). Notably, it is widely established within the
296 scientific community that certain ocean-atmospheric teleconnections, such as ENSO, can profoundly influence the
297 onset of drought conditions in various regions worldwide, particularly in the tropics (Ropelewski and Halpert,
298 1987; Shabbar and Skinner, 2004; Hoell et al., 2014; Vicente-Serrano et al., 2017). For instance, during the peak
299 phase of El Niño or La Niña in the tropical Pacific, a corresponding change in precipitation patterns can be
300 observed several months later in North American winter climate (Livezey and Smith, 1999; Hoerling and Kumar,
301 2003). This delayed impact provides a crucial window for predicting potential drought conditions with a long lead
302 time exceeding one month (Johnson and Xie, 2010). Moreover, this lagged correlation allows for proactive drought
303 management strategies, with the ability to anticipate and prepare for drought conditions based on forecasted ENSO

304 conditions. Nevertheless, drought predictability is seasonally and spatially variable. Typically, the accuracy of
305 seasonal drought prediction is superior in the tropics, while it still challenging in the extra-tropics (Doblas-Reyes
306 et al., 2013).

307 In the MedR, the response of climate to ENSO is complex. It varies over time and depends on the maturity of the
308 ENSO state, and the co-occurrence with NAO (Kim and Raible, 2021; Brönnimann et al., 2007; Mariotti et al.,
309 2002). Although many authors have found a non-negligible correlation between ENSO and precipitation anomalies
310 in the MedR, it remains insignificant compared to the tropics (Mariotti et al., 2002).

311 In contrast, the NAO is commonly identified as a prominent factor influencing Mediterranean climate variability
312 during the winter season (Ulbrich and Christoph, 1999; Vicente-Serrano et al., 2011; Kahya, 2011; Santos et al.,
313 2014; Cook et al., 2016). It is important to note, however, that while acknowledging the profound impact of the
314 NAO on the climate dynamics of the MedR, its predictability, especially on seasonal scales, continues to be a
315 considerable challenge in the field of climate science (Czaja and Frankignoul, 1999; Saunders and Qian, 2002;
316 Scaife et al., 2014; Dunstone et al., 2016).

317 During the positive phase of the NAO, below-average precipitation rates are observed over large parts of the
318 northern and western MedR. While in the negative phase of NAO, the climate is wetter and warmer (Lionello,
319 2012). Kim and Raible (2021) analyzed the dynamics of multi-year droughts over the western and central
320 Mediterranean for the period of 850–2099. This analysis suggests Mediterranean droughts from 850-1849 CE were
321 mainly driven by the internal variability of the climate system, including elements like barotropic high-pressure
322 systems, positive NAO phases, and La Niña-like conditions. Conversely, external forcing such as volcanic
323 eruptions were found to be associated with wetter Mediterranean conditions. In the period 1850-2099 CE, however,
324 anthropogenic influences amplified land-atmosphere feedback, leading to persistent dry conditions in the
325 Mediterranean (Kim and Raible, 2021).

326 Paz et al. (2003) analyzed monthly mean Sea Level Pressure anomalies (SLP) from the 1958–1997 record over
327 the Mediterranean Basin. They identified a significant anomalous SLP oscillation between North Africa (NA) and
328 West Asia (WA) and concluded that the regional trend of the NAWA index could explain increased drought
329 processes in the eastern Mediterranean after the late '70s, in relation to northern hemispheric circulation.

330 The climate heterogeneity in the Mediterranean area may also be explained by the regional Mediterranean
331 Oscillation (MO) characterized by the opposite precipitation patterns between the eastern and western regions
332 (Düneloh and Jacobeit, 2003). More recently Redolat et al. (2019) proposed a new version of MO that uses areas
333 instead of observatories or isolated points. The new index which is referred to as the Upper-Level Mediterranean
334 Oscillation index (ULMOi) is based on the differences in geopotential height at 500 hPa to improve the
335 predictability of seasonal anomalies in the Mediterranean climate (Redolat et al., 2019). According to this study,
336 ULMOi has reported higher confidence than the MO index for rainfall predictability (Redolat et al., 2019). Other
337 teleconnections influencing the climate of MedR can be found in the reviews done by Paz et al. (2003) and Lionello
338 (2012). Recent works have also shed light on the impact of Madden Julian Oscillation (MJO) on water availability
339 in the region, especially during heavy rainy episodes, see for example (Chaqdid et al., 2023)

340 In conclusion, several complex factors that influence the predictability of drought are not yet fully understood,
341 especially those related to climate change. Therefore, more research on the physical mechanisms causing drought
342 in the MedR is needed to improve the predictability of drought forecasts.

343 Expanding our grasp of the physical factors causing drought in MedR, we will now delve into drought forecasting
344 models. By leveraging insights from these mechanisms, scientists have developed numerous approaches and
345 techniques including statistical, dynamical, and hybrid statistical-dynamical models to boost the accuracy and
346 trustworthiness of drought predictions.

347 **4 Statistical Drought Prediction Methods**

348 Once the major sources of predictability are identified, the task of the statistical models is to uncover the spatial
349 and/or temporal relationship between a set of these potential predictors and the predictand. When a large number
350 of predictors are identified within the same region, dimension reduction techniques like Principal Component
351 Analysis (PCA) or Linear Discriminant Analysis (LDA) can improve model accuracy and efficiency by reducing
352 the number of dimensions while preserving essential information. On the other hand, feature selection methods
353 such as decision trees or Random Forests can help eliminate irrelevant predictors. These approaches can prevent
354 overfitting, leading to enhanced model performance and interpretability (Hao et al., 2018; Ribeiro and Pires, 2016).

355 The next sections will present the frequently used data-driven models and how they were employed to predict
356 different types of droughts at different spatiotemporal resolutions in the MedR.

357 **4.1. Time Series models**

358 During the last few decades, several methods have been developed to analyze the stochastic characteristics of
359 hydrologic time series (Morid et al., 2007; Rafiei-Sardooi et al., 2018; Band et al., 2022; Zarei and Mahmoudi,
360 2020). Moving average (MA), Autoregressive (AR), and Autoregressive Integrated Moving Average (ARIMA)
361 are all linear models that analyze past observations of the same variable to predict its future values. Normality and
362 stationarity of observations are two of the basic assumptions of these time-series models. Therefore, if some trends
363 or seasonality are detected in observations, they should be removed before the modeling to avoid any drift in the
364 concepts to be captured.

365 ARIMA is the most frequently used time-series model (Zhang et al., 2003). The popularity of this model is related
366 to its ability to search systematically for an adequate model at each step of the model building (identification,
367 parameter approximation, and diagnostic check). This method is based on the concept that nonstationary data could
368 be made stationary by “differencing” the series (Box et al., 2015). The approach involved considering a value Y
369 at time point t and adding/subtracting based on the Y values at previous time points and adding/subtracting error
370 terms from previous time points. The formula can be written as:

$$Y_t = c + \varphi_1 Y_{t-1} + \dots + \varphi_p Y_{t-p} + \theta_1 e_{t-1} + \dots + \theta_q e_{t-q} + e_t, \quad (1)$$

371 where:

372 Y_t is the value of the variable at time t ; c is a constant term; p and q are the orders of AR and MA models,
373 respectively; φ_i and θ_i are model parameters; $e_{t-1} \dots e_t$ are the error terms.

374 The AR component captures the impact of past values on the current value, the I component handles any non-
375 stationarity in the data (i.e., changes in the mean or variance over time) by “differencing” the time series, and the
376 MA component captures the impact of random shocks or errors in the data.

377 The ARIMA model is generally expressed with the three terms p, d, and q. The order of differencing in the I
378 component is denoted by the value of (d) in the ARIMA(p,d,q) notation. It represents the number of times that the
379 data must be “differenced” to produce a stationary signal. The lag order (p) represents the number of prior
380 observations having a strong correlation with the current observation. While (q) is the size of the moving window
381 and is identified by determining the number of lag errors that have a significant impact on the current observation.

382 The SARIMA is a more specific version of ARIMA that includes a seasonal component, which takes into account
383 the repeating patterns that occur at regular intervals (e.g., daily, weekly, monthly) in the data. This makes it more
384 appropriate for forecasting seasonal time series data.

385 Bouznad et al. (2021) conducted a comparative analysis of ARIMA and SARIMA models using precipitation,
386 temperature, and evapotranspiration data to assess seasonal drought conditions in the Algerian highlands. These
387 models were compared based on their ability to replicate and forecast the data series accurately. The SARIMA
388 model emerged as the better choice as it exhibited significant p-values for all variables under study. This implies
389 that the model was statistically significant in predicting the variables and thus outperformed the ARIMA model in
390 this specific context. In the same country, Achite et al. (2022) investigated the meteorological and hydrological
391 drought in the Wadi Ouahrane Basin using ARIMA and SARIMA models applied to SPI and SRI indices. A
392 validation based on R² revealed high accuracy for SPI and SRI of 0.96 and 0.97 respectively, at 1-month lag.
393 Additional examples of the use of the time-series model in drought forecasting in MedR can be found in Table 1.

394 Although time series models have shown good predictability of drought characteristics, these methods present
395 certain limitations as they are based solely on the persistence of some drought indicators (trend, seasonality)
396 without worrying about their interactions.

397 **Table 1 Main studies using the Time series model to forecast drought in the MedR.**

398 **4.2. Regression analysis**

399 Regression models are commonly applied in drought forecasting due to their straightforwardness, interpretability,
400 and proficiency in revealing potential connections between hydroclimatic variables. These models use various
401 predictors (independent variables), including precipitation, temperature, and other relevant climate indices, to
402 approximate drought indices or related target variables (dependent variables).

403 Simple and multivariate linear regression (MLR) models have been broadly applied for projecting extreme
404 hydrological phenomena such as droughts (Sharma et al., 2018). These models shed light on the linear connections
405 between various predictors and predictands, offering a valuable method to understand the primary factors of
406 drought conditions and their interactions (Mishra et al., 2011).

407 An MLR model that predicts drought from multiple drought predictors X_1, X_2, \dots, X_n can be formulated as:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_n X_n + \varepsilon \quad (2)$$

408 Where:

409 β_0 is the y-intercept or the constant term,

410 $\beta_{i(i=1,2,\dots,n)}$ are the regression coefficient for each independent variable $X_{i(i=1,2,\dots,n)}$,

411 ε is the model's error term.

412 On the other hand, when drought forecasts have a binary or dichotomous nature, such as drought vs. no drought,
413 logistic regression models can be particularly useful. In these cases, the dependent variable (drought) is expressed
414 as a probability or likelihood of occurrence. The main goal of logistic regression is to estimate the relationship
415 between a set of predictors and the probability of the binary outcome (Rahali et al., 2021; Hosmer et al., 2013).

416 Some of the applications of regression analysis for drought forecasting in the MedR are discussed below and
417 summarized in (Table 2).

418 **Table 2 Main studies using regression analysis to forecast drought in the MedR.**

419 Sousa et al. (2011) analyzed the spatiotemporal evolution of drought conditions across the MedR during the 20th
420 century using monthly precipitations, NAO, and SST as independent variables and scPDSI as a dependent variable.
421 Their study successfully developed a robust stepwise regression model capable of predicting summer drought
422 conditions six months in advance with a high correlation of 0.79 between simulated and observed scPDSI time
423 series, thus demonstrating its utility in forecasting future drought conditions in the region. Tigkas and Tsakiris
424 (2015) used the MLR model with variables that include the minimum temperature and RDI as the main
425 independent variable for the assessment of drought effects on wheat yield in two rural areas of Greece. The results
426 of this analysis showed a high correlation between RDI and the wheat yield during the winter months which proves
427 that satisfactory prediction of the drought impacts on wheat yields 2 to 3 months before the harvest can be achieved
428 using the MLR model. Martínez-Fernández et al. (2016) conducted a study in the REMEDHUS (Soil Moisture
429 Measurement Stations Network) area in Spain, aiming to monitor agricultural drought on a weekly time scale and
430 provide early warning to farmers for adapting irrigation strategies. They computed a specific agricultural drought
431 index (SWDI) using data from the SMOS satellite. Within this study, various computation approaches were
432 analyzed, and the ones that yielded the most promising results were those directly based on soil attributes or
433 parameters extracted from pedo-transfer function (PTF). These approaches utilized a multiple regression analysis,
434 with soil water parameters as dependent variables and incorporated other relevant soil characteristics such as
435 texture, bulk density, and porosity.

436 Although regression models have been valuable in drought forecasting, they exhibit certain limitations such as the
437 linearity assumption, limited interactions between variables, sensitivity to overfitting and multicollinearity (Rafiei-
438 Sardooi et al., 2018). Consequently, their ability to accurately represent complex real-world phenomena is often
439 insufficient (Zhang, 2003). To address these shortcomings, more advanced models capable of capturing non-linear
440 relationships and interactions are required, ultimately improving the forecasting of complex hydroclimatic events
441 such as droughts.

442 4.3. Machine Learning and Hybrid Models

443 One of the big challenges in drought prediction is the random and nonlinear nature of the hydroclimatic variables
444 (Agana and Homaifar, 2017). Over the last two decades, intelligent techniques such as Artificial Neural networks
445 (ANN), Support Vector Machines (SVM), and Fuzzy Logic (FL) have proven to be very promising tools for
446 modeling nonlinear and dynamic time series (Mokhtarzad et al., 2017; Dikshit et al., 2022; Prodhan et al., 2022).
447 These algorithms have thus garnered significant interest in the realms of drought modeling and forecasting
448 (Prodhan et al., 2022). In the context of modeling, they are used to develop mathematical representations of
449 complex drought systems, capturing the interplay of various atmospheric, hydrological, and land surface processes
450 that lead to these phenomena. In forecasting, the models derived from these algorithms are employed to anticipate
451 future drought conditions, assisting in risk assessment and mitigation strategies. Table 3 highlights key studies that
452 utilize machine learning models for drought prediction in the MedR.

453 Prodhan et al. (2022) stated in their review of machine learning methods for drought hazard monitoring and
454 forecasting on a global scale that the ANN was the most popular model in peer-reviewed literature, and they
455 suggested that higher use of the ANN model is anticipated because it has non-linear properties that make it more
456 robust for identifying all possible interactions between predictors.

457 ANN is a mathematical model inspired by biological brain neural networks. It consists of an interconnected group
458 of nodes (artificial neurons) and processes information using a connectionist computation (Fig. 2). In the case of
459 drought forecasting, ANN architecture is usually made of three layers: an input layer which consists of the drought
460 predictors, hidden layer(s) which comprises a function that applies weights to the input variables and passes them
461 using a non-linear activation function, and an output layer that consists of the drought target variable or drought
462 index (Han and Singh, 2020).

463 **Figure 2 Drought forecasting based on a simple ANN architecture.**

464 For the proper functioning of a neural network, the optimization of network weights (known as the learning or
465 training process) is an essential step (Dikshit et al., 2022). Back-propagation, Feed Forward, Gradient Descent,
466 Stochastic Gradient Descent, Adam and Levenberg–Marquardt are among the common training algorithms
467 (Bergou et al., 2020). The role of these algorithms is to minimize the difference between predicted and observed
468 values by adjusting the network weights and biases of the model.

469 Di Nunno et al. (2021) used a non-linear AutoRegressive with eXogenous inputs (NARX) neural network (a
470 particular type of recurrent dynamic ANNs) to predict spring flows in the Umbria region (Italy). The results of this
471 study show a good performance of the NARX model in predicting spring discharges for both short (1 month:
472 $R^2 = 0.90\text{--}0.98$, $RAE = 0.09\text{--}0.25$) and long-term lag time (12 months: $R^2 = 0.90\text{--}0.98$, $RAE = 0.09\text{--}0.24$).
473 Achour et al. (2020) also confirmed the performance of the ANN model with multi-layer perceptron networks
474 architecture and Levenberg–Marquardt calibration algorithm in predicting drought in seven plains located in
475 northwestern Algeria with 2 months lead time ($R^2=0.81$, $RMSE<0.41$ and $MAE<0.23$).

476 SVM is also a robust supervised learning model that investigates data for classification and regression analysis. It
477 designates the best separating line to classify the data with more safety margins. Besides, the good performance in
478 solving linear problems, SVM could also transfer a non-linear classification to a linear one using the kernel
479 function and be able to solve high-dimensional problems (El Aissaoui et al., 2021).

480 In the context of drought studies, SVM is particularly beneficial due to its ability to handle many inputs, use a
481 small dataset for training, and its resistance to overfitting compared to ANN (Hao et al., 2018). These features
482 make SVM less sensitive to data sample size, enhancing the robustness of the drought model. On the forecasting
483 aspect, SVM employs a kernel function to map predictors in a high-dimensional hidden space, subsequently
484 transforming the predictand to the output space (El Aissaoui et al., 2021). This process allows the SVM model to
485 generate effective and accurate forecasts about potential future drought events, given the input variables.

486 El Aissaoui et al. (2021) used the Support Vector Regression (SVR) model with three kernel functions (linear,
487 sigmoid, polynomial, and radial basis function [RBF]) for the prediction of drought in the region of Upper
488 Moulouya (Morocco) through the SPI and SPEI indices. Their research underscores the SVR model's effectiveness,
489 particularly with the RBF kernel function, in forecasting drought indices SPI ($R = 0.92$) and SPEI ($R = 0.89$).
490 Mohammed et al. (2022) evaluated the applicability of 4 Machine Learning algorithms namely bagging (BG),
491 random subspace (RSS), random tree (RT), and random forest (RF) in predicting agricultural and hydrological
492 drought events in the eastern MedR based on SPI. The results of this study revealed that hydrological drought
493 (SPI-12, -24) was more severe over the study area and BG was the best model in the validation stage with RMSE
494 ≈ 0.62 – 0.83 and $r \approx 0.58$ – 0.79 .

495 To further improve the prediction accuracy of AI models, preprocessing of data using wavelet decomposition
496 (WD), PCA, or empirical mode decomposition (EMD) is recommended. These techniques known as hybrid models
497 have gained attention due to their potential to improve prediction accuracy and better capture complex
498 relationships in the data (Yoo et al., 2015; Liu et al., 2020). The preprocessing techniques are used to extract and
499 represent the essential features and patterns within the data and statistical methods, such as ANN, SVM, or RF,
500 model the relationship between the input variables and the target drought index. El Ibrahim and Baali (2018)
501 explored the prediction of short-term (SPI-3) and long-term (SPI-12) drought conditions using 6 models: SVR,
502 ANN-MLP, Adaptive Neuro-Fuzzy Inference Systems (ANFIS), WA-SVR, WA-MLP, and WAANFIS in the
503 Saïss Plain (Morocco). They argued that ANN models were more efficient than SVR models and that the use of
504 wavelet analysis has enhanced the prediction skill of ANN models which is probably due to their capacity in
505 detecting local discontinuities and non-stationary characteristics of the data.

506 **Table 3 Main studies using Artificial Intelligence Models to forecast drought in the MedR.**

507 Özger et al. (2020) evaluated the effect of using EMD and WD for decomposing time series data on drought
508 prediction using the self-calibrated Palmer Drought Severity Index (sc-PDSI) and machine learning models ANN
509 and SVM. They found that the accuracy of standalone machine learning models in midterm sc-PDSI predictions
510 was unsatisfactory, but it significantly improved when EMD and WD techniques were introduced, particularly for
511 hybrid wavelet models.

512 In summary, machine learning and hybrid models, which combine preprocessing techniques with statistical
513 methods, have demonstrated their efficiency in drought forecasting, as they can effectively handle intricate,
514 nonlinear relationships and adjust to a diverse range of input data characteristics. However, the applicability of
515 these models may be challenging when input variables exhibit strong dependence on each other. This dependency
516 can lead to several issues such as multicollinearity, overfitting, and diminishing returns (Maloney et al., 2012). To

517 address these limitations and improve drought forecasting performance, it is essential to consider joint probability
518 models (Madadgar et al., 2014; Hao et al., 2018).

519 **4.4. Joint Probability Models**

520 The probabilistic analysis of drought events plays a significant role in the planning and management of water
521 resource systems, particularly in arid or semi-arid Mediterranean regions known for low annual and seasonal
522 precipitation. Drought return periods, which estimate the frequency of drought events, can provide valuable
523 information for responsible water management during drought conditions. The univariate frequency analysis is a
524 common method for analyzing drought events. As mentioned above, drought is usually characterized by its
525 severity, duration, and frequency which can be extracted using the theory of runs introduced by Yevjevich (1967).
526 These characteristics present a dependence structure that can be ignored by the univariate approach, resulting in
527 an under/overestimation of drought risks. As such, several joint probability theories have been recently
528 incorporated into drought risk analysis including two or more variables. One of the most important joint probability
529 models that have garnered increasing attention in the hydrologic community over the last decade is the copula
530 model (Jehanzaib et al., 2021; Pontes Filho et al., 2020; Das et al., 2020; Zellou and Rahali, 2019; Mortuza et al.,
531 2019; Ozga-Zielinski et al., 2016; Xu et al., 2015; AghaKouchak, 2014b; Madadgar and Moradkhani, 2013; Chen
532 et al., 2013).

533 There are numerous copula families and classes, such as elliptic, Archimedean (Clayton, Frank, Gumbel, Joe),
534 extreme value, and Bayesian to cite but a few. The choice of the most suitable copula family depends on the
535 specific modeling goals and the structure of the data being modeled (Genest and Favre, 2007 ; Joe, 2014).

536 A brief overview of the bivariate copula theory is given here to initiate readers about their concept and application.
537 However, for additional details on the theory and concepts of the copula, readers may refer to the monographs by
538 Joe (1997) and Nelsen (2007). Furthermore, comprehensive methodological understanding of constructing high-
539 dimensional copulas, such as Pair Copula Construction (PCC) and Nested Archimedean Construction (NAC), can
540 be garnered from the works of Aas and Berg (2009) and Savu and Trede (2010).

541 Let F be a 2-dimensional distribution function, with univariate margins F_1 and F_2 for random variables U and V ,
542 respectively. According to Sklar's theorem (Sklar, 1959), there exists a copula C such that:

$$F(U, V) = C(F_1(U), F_2(V)) \quad U, V \in R \quad (3)$$

543 with C unique when $F_1(U)$ and $F_2(V)$ are continuous marginal distributions, so that

544 $C: [0,1]^2 \rightarrow [0,1]$ that satisfies the boundary conditions $C(u, 0) = C(0, v) = 0$

545 and $C(u, 1) = C(1, u) = u$ (Uniform margins) for any $u \in [0,1]$ and the so-called 2-increasing property
546 (Papaioannou et al., 2016).

547 The main advantage of the copula over the traditional multivariate distributions is its ability to model the nonlinear
548 dependence structure between variables independently from the choice of their marginal distributions (Salvadori
549 and De Michele, 2004). This concept simplifies the joint probability analysis and its application in high dimensions
550 (with a large number of variables or predictors) becomes possible.

551 Serinaldi et al. (2009) constructed a four-dimensional joint distribution using the copula approach and SPI to model
552 the stochastic structure of drought variables in Sicily (Italy). Drought return periods were next computed as mean
553 interarrival time, taking into account two drought characteristics at a time by means of the corresponding bivariate
554 marginals of the fitted four-dimensional distribution. Bouabdelli et al. (2020) investigated the joint probability and
555 joint return period of drought severity and duration using copula theory to assess the hydrological drought risk in
556 the reference period and its probability of occurrence in the future under two climate change scenarios in three
557 basins located in northern Algeria. Bonaccorso et al. (2015) evaluated the conditional probability of future SPI
558 classes under the hypothesis of multivariate normal distribution of NAO and SPI series in Sicily (Italy). The results
559 of this study indicated that transition probabilities toward equal or worse drought conditions increase as NAO
560 tends toward extremely positive values. Table 4 displays additional examples of the application of the Joint
561 Probability Models to forecast drought in the MedR.

562 **Table 4 Main studies using Joint Probability Models to forecast drought in the MedR.**

563 All the above-mentioned studies confirm that copulas can accurately capture the joint distribution and dependence
564 structure between multiple drought predictors without making strong assumptions about their marginal
565 distributions. By combining the strengths of machine learning models with the flexibility of copulas, researchers
566 can develop more accurate and reliable hybrid methods that better represent the intricacies of hydrological
567 processes and climatic variables, even in the presence of strong dependence among the input variables (Jiang et
568 al., 2023; Li et al., 2022; Wu et al., 2022; Zhu et al., 2020).

569 **4.5. Ensemble Streamflow Prediction**

570 The ESP method, a commonly used technique in hydrological forecasting, was primarily intended for medium to
571 long-term streamflow prediction (Day, 1985). However, its utility extends to the prediction of hydrological
572 droughts, characterized by low streamflows (KyungHwan and DegHyo, 2015 ; Sutanto et al., 2020 ; Troin et al.,
573 2021).

574 ESP operates on the principle of employing historical data to generate an ensemble of possible future climate
575 conditions (Turco et al., 2017b). The process begins by determining the current state of the system, considering
576 parameters such as current streamflow, soil moisture levels, and reservoir levels which serves as the initial
577 conditions for the forecast (Wood et al., 2016). The generation of the ensemble involves choosing a historical
578 record at each time (day, week or month) of forecast that will provide the meteorological inputs (Day, 1985). By
579 repeating this process for every time in the historical record, an ensemble of forecasts is produced, each member
580 representing a potential future scenario. The hydrological model is run for each ensemble member, using the
581 chosen meteorological inputs and initial conditions to generate a range of potential future states of the system
582 (Harrigan et al., 2018). The ensemble of forecasts is then analyzed to derive probabilistic predictions.

583 As new data becomes available, forecasts can be updated by re-initializing the system's state and generating a new
584 ensemble of forecasts. A significant advantage of this method is that it enables the uncertainty prediction by
585 producing a variety of potential future streamflow forecast scenarios which can increase the confidence of this
586 approach, specifically for its operational use in water management (Troin et al., 2021).

587 However, the limitations of the ESP method must be noted. For instance, it presupposes that future behavior will
588 mirror past behavior, a concept that may not hold under changing climatic conditions (Wood et al., 2016).
589 Furthermore, the method's performance is heavily reliant on the quality and duration of the historical
590 meteorological records used in the ensemble generation process (Turco et al., 2017b).

591 ESP is frequently employed as a benchmark for comparison with more sophisticated forecasting methods, such as
592 dynamical climate models or hybrid statistical-dynamical models (AghaKouchak, 2014a; Turco et al., 2017b;
593 Torres-Vázquez et al., 2023). Although these more complex methods can outperform ESP in some instances, the
594 computationally efficient ESP method often exhibits comparable performance, particularly when forecasting a few
595 months ahead (Turco et al., 2017b; Torres-Vázquez et al., 2023).

596 4.6. Markov Chain Models

597 Markov chains are effective tools to understand the stochastic characteristics of drought events and their temporal
598 dependency. These models assume that future states depend only on the current state.

599 Mathematically, Markov chain is a stochastic process X , such as at any time t , X_{t+1} is conditionally independent
600 from $X_0, X_1, X_2, \dots, X_{t-1}$, given X_t ; the probability that X_{t+1} takes a particular value j depends on the past only
601 through its most recent value X_t :

$$P\{X_{t+1} = j | X_0, X_1, \dots, X_t\} = P\{X_{t+1} = j | X_t = i\} \forall i, j \in S, t \in T \quad (4)$$

602 A Markov chain is characterized by a set of states, S , and by the transition probability, P_{ij} , between states. The
603 transition probability P_{ij} is the probability that the Markov chain is at the next time point in state j , given that it is
604 at the present time point in state i .

605 The drought prediction using this concept can be expressed as the transition from wet or normal state to dry state
606 (or the other way around) or the transition from one drought severity state to another (e.g., no drought, mild
607 drought, moderate drought, extreme drought). Habibi et al. (2018) studied meteorological drought in North
608 Algeria's Chélif–Zahrez basin, employing both localized and spatially distributed probabilities for temporal
609 transitions using Markov Chains, and recurrence probabilities using an optimal time series model, the APARCH
610 approach. Paulo and Pereira (2007) used Markov chains, incorporating homogeneous and non-homogeneous
611 formulations, to predict drought transitions up to three months ahead, based on the SPI derived from 67 years of
612 data in Southern Portugal. The non-homogeneous Markov model outperformed its counterpart by considering the
613 initial month and seasonal rainfall variations. Table 5 lists additional studies that apply Markov chain models for
614 MedR drought forecasting.

615 Table 5 Main studies using Markov Chains Model to forecast drought in the MedR.

616 These studies generally support the effectiveness of Markov chain models in providing valuable drought insights.
617 However, it is essential to consider the challenges associated with applying Markov chains within the MedR, as
618 the region's complex topography, considerable interannual climate fluctuations, limited data availability, and the
619 non-stationarity resulting from climate change can adversely affect the models' core assumptions and constrain
620 their long-term forecasting accuracy. Addressing these challenges calls for the adoption of more sophisticated

621 techniques that encompass both stochastic and physically based approaches, ultimately enhancing the accuracy
622 and reliability of drought predictions in this region (Paulo and Pereira, 2007).

623 **5 Dynamical Drought Prediction Methods**

624 Dynamical drought prediction methods are generally based on the use of seasonal climate forecasts derived from
625 comprehensive GCMs. The European Centre for Medium-Range Weather Forecasts (ECMWF)'s System 4
626 (SYS4), the Hadley Centre's Global Environmental Model (HadGEM), the Community Earth System Model
627 (CESM), and the National Centers for Environmental Prediction (NCEP)'s Climate Forecast System (CFS) are
628 some widely recognized examples. Designed to emulate physical processes across the atmosphere, ocean, and land
629 surface, these GCMs can produce near-term forecasts for various climatic factors such as precipitation,
630 temperature, surface pressure, and winds. However, these models typically provide a global overview and possess
631 a relatively coarse resolution, which spans from 150 km to 300 km horizontally, encompassing 10 to 20 vertical
632 atmospheric layers and up to 30 oceanic layers. This level of detail may not offer the specificity necessary for
633 local-scale impact assessments. To counter this, post-processing steps, encompassing downscaling and bias
634 correction, are crucial when employing GCM forecasts (Tuel et al., 2021; Gumus et al., 2023). The main objective
635 here is to refine the global, coarse-grained GCM data into higher-resolution forecasts. These refined forecasts are
636 far more pertinent for predicting seasonal drought events at a regional and local scale within the MedR.

637 The most common approaches to downscale GCM forecasts include statistical models, dynamic or nested models,
638 and hybrid statistical–dynamical models (Wilby et al., 2004). In statistical downscaling, large-scale variables are
639 used as the predictors and desired near-surface climate variables are the predictands (Gutiérrez et al., 2019). The
640 role of statistical models is then to measure the correlations between predictors and predictands. Whereas
641 dynamical downscaling refers to the use of high-resolution regional simulations to dynamically extrapolate the
642 effects of large-scale climate processes to regional or local scales based on a nesting approach between GCMs and
643 Regional Climate Models (RCMs) (Giorgi and Gutowski, 2015). However, it is known that GCMs contain
644 significant systematic biases that may propagate into RCMs through the lateral and lower boundary conditions
645 and thus degrade the dynamically downscaled simulations and lead to large uncertainties (Maraun, 2016). Besides,
646 climate predictions from a single climate model simulation are sensitive to initial oceanic and atmospheric states
647 and can represent only one of the possible pathways the climate system might follow.

648 **5.1. Multi-Model Ensemble**

649 To allow probabilistic estimates of climate variables with uncertainties in quantification, it is necessary to carry
650 out an ensemble of simulations with different initial conditions from each model and to combine various models
651 as ensemble members. The frequently used Multi-Model Ensemble (MME) and bias correction methods include
652 quantile mapping (Wood et al., 2002) and Bayesian Model Averaging (Krishnamurti et al., 1999; Seifi et al., 2022).
653 These methods proceed by adjusting the modeled mean, variance, and/or higher moments of the distribution of
654 climate variables, to match the observations. However, such MME simulations can be very computationally
655 demanding. Therefore, some international dynamical downscaling intercomparison projects were carried out such
656 as the Coordinated Regional Downscaling Experiment (CORDEX, Wilby et al., 1998) and its Mediterranean
657 initiative MEdCORDEX (Ruti et al., 2016) to provide present and future climate simulations with a high spatial

658 resolution (~12 km). In a study conducted by Turco et al. (2017b), the accuracy and reliability of ECMWF's System
659 4 (SYS4) in forecasting drought conditions, characterized by a six-month SPEI6, across Europe from 1981 to 2010
660 was evaluated. They found that the SYS4 model effectively projected the spatial patterns of SPEI6 and various
661 drought conditions (ranging from extreme to normal) with a reasonable degree of precision up to a lead time of 2
662 months. In the same geographical context, Ceglar et al. (2017) demonstrate the power of dynamical models in the
663 agricultural sector by investigating the relationship between large-scale atmospheric circulation and crop yields in
664 Europe. Their research highlights the significant potential of such models in developing effective seasonal crop
665 yield forecasting, and consequently, in advancing dynamic adaptation strategies to climate variability and change.

666 All these studies confirmed the good performance of MME methods in providing probabilistic drought forecasts
667 for 1 to 2 months of lead time and improving drought onset detectability. However, much effort should be made
668 in selecting the most skilled GCM ensembles in reproducing the large and synoptic scale atmospheric and land-
669 surface conditions associated with drought development in the MedR. By prioritizing ensembles that adequately
670 capture the region's distinct climate characteristics, spatial-temporal variability, and land-atmosphere interactions,
671 the MME forecasts can mitigate biases related to key meteorological variables such as temperature or precipitation
672 and significantly improve the precision and reliability of drought predictions (Li et al., 2023; Ahmed et al., 2019).

673 **5.2. Coupled hydrological models.**

674 On the other hand, GCMs often struggle to accurately represent some complex elements of the hydrological cycle,
675 such as soil moisture, streamflow, groundwater level, and PET. The inherent complexities of these variables and
676 the broad spatial scale of GCMs make it challenging to fully capture their behavior. This gap can limit the
677 effectiveness of GCMs in drought prediction and modelling (Balting et al., 2021). Consequently, to dynamically
678 forecast agricultural and hydrological droughts, the water balance should be correctly simulated by hydrological
679 models forced by climate forecasts (Wanders and Wood, 2016). Among the most used models to forecast
680 hydrological drought, we cite, the Soil and Water Assessment Tool (SWAT) (Arnold et al., 1998), the Variable
681 Infiltration Capacity (VIC) (Liang et al., 1994), and the Community Land Model (CLM) (Oleson et al., 2004).
682 These models can incorporate data on soil moisture, vegetation, snow water equivalent, groundwater level, and
683 other initial hydrologic conditions with climate forecasts to simulate the movement of water through the
684 hydrological cycle, including the processes of precipitation, evaporation, infiltration, and runoff. Crop growth
685 models can also be coupled with hydrological models to make an accurate prediction of agricultural drought and
686 its impact on crop yields (Narasimhan and Srinivasan, 2005; Abhishek et al., 2021).

687 Coupled hydroclimatic models can improve drought forecasting by allowing for the consideration of feedback
688 between the hydrological and climatological components of the Earth system. Indeed, drought conditions can
689 affect the availability of water for evapotranspiration, which in turn can affect the amount of moisture in the
690 atmosphere and the likelihood of precipitation. By incorporating this feedback into the model, it is possible to
691 produce more accurate forecasts of drought conditions.

692 In a recent study, Brouziyne et al. (2020) combined meteorological and hydrological drought indices (SPI and
693 SDI) with a SWAT model forced by bias-corrected CNRM-CM5 data to predict future droughts under two RCPs
694 (4.5 & 8.5) in Bouregreg watershed, Morocco. They confirmed that using multiple drought indices and a
695 comprehensive water budget indicator such as Total Water Yield provided a valid approach to evaluate drought

696 conditions in a Mediterranean context. Marx et al. (2018) analyzed a multi-model ensemble of 45 hydrological
697 simulations based on three RCPs (2.6, 6.0, and 8.5), five GCMs (CMIP5), and three state-of-the-art hydrological
698 models (mHM, Noah-MP, and PCR-GLOBWB) to investigate how hydrological low flows are affected under
699 different levels of future global warming. Based on the analysis of the results, the authors recommended using
700 multiple hydrological models in climate impact studies and to embrace uncertain information on the multi-model
701 ensemble as well as its single members in the adaptation process.

702 **5.3. Long-term drought projection under climate change.**

703 As climate change continues to influence drought events in the MedR, it is vital to integrate long-term climate
704 projections into drought forecasting strategies (Tramblay et al., 2020). In this regard, GCMs are essential for
705 projecting future climate changes under varying scenarios, such as Representative Concentration Pathways (RCPs)
706 or Shared Socioeconomic Pathways (SSPs¹). Coupled with downscaling techniques, these models offer region-
707 specific projections of critical climate variables including precipitation, temperature, surface pressure, and winds.
708 These projections are instrumental in estimating long-term drought events, facilitating a more comprehensive risk
709 assessment for stakeholders and decision makers. Baronetti et al. (2022) analyzed the expected characteristics of
710 drought episodes in the near (2021–2050) and far (2071–2100) future compared to the baseline conditions (1971–
711 2000) for northern Italy using EURO-CORDEX and MedCORDEX GCMs/RCMs pairs at a spatial resolution of
712 0.11 degrees for the RCPs (4.5 and 8.5) scenarios. The results indicated that the GCM/RCM pairs performed
713 generally well, while in complex environments such as coastal areas and mountain regions, the simulations were
714 affected by considerable uncertainty. Dubrovský et al. (2014) used an ensemble of 16 GCMs to map future drought
715 and climate variability in the MedR. Bağçacı et al. (2021) compared the capacity of the latest release Coupled
716 Model Intercomparison Project Phase 6 (CMIP6) model ensembles in representing near-surface temperature and
717 precipitation of Turkey in comparison with its predecessor CMIP5 to better understand the vulnerability degree of
718 the country to climate change. In a study conducted by Cos et al. (2022), the authors compared climate projections
719 from CMIP5 and CMIP6 models to assess the impacts of climate change in the MedR. The findings reveal a robust
720 and significant warming trend across all seasons, with CMIP6 models projecting stronger warming compared to
721 CMIP5. While precipitation changes show greater uncertainties, a robust and significant decline is projected over
722 large parts of the region during summer by the end of the century, particularly under high emission scenarios.
723 (Seker and Gumus, 2022) uses 22 global circulation models from CMIP6 to project future precipitation and
724 temperature changes in the MedR. The MMEs outperform individual GCMs in simulating historical data, and the
725 projections indicate a decrease in precipitation by 15% for SSP2–4.5 and 20% for SSP5–8.5. Table 6 shows the
726 main studies using dynamical models to forecast drought in MedR.

727 **Table 6 Main studies using dynamical models to forecast drought in the MedR.**

728 In summary, recent advancements in seasonal drought forecasting with dynamical models encompass increased
729 climate resolution, improved representation of physical processes, improved initialization methods using data
730 assimilation techniques (Zhou et al., 2022), use of multi-model ensembles (Wanders and Wood, 2016; Seker and
731 Gumus, 2022), coupled modeling approaches (Guion et al., 2022), and the development of sub-seasonal to seasonal

¹ SSPs are the latest climate change scenarios used in CMIP6. They not only incorporate greenhouse gas emissions scenarios like their predecessor, RCPs from CMIP5, but also integrate socioeconomic factors, such as population growth, economic development, and technological progress. Essentially, SSPs provide a more holistic view of possible future climate scenarios by considering both environmental and societal changes.

732 predictions (Zhou et al., 2021). These steps have contributed to more accurate and reliable drought predictions.
733 However, even with these improvements, predicting drought months in advance remains a significant challenge
734 due to the inherent complexity and chaos of the climate system.

735 **6 Hybrid Statistical-Dynamic Methods**

736 While statistical models, when appropriately fine-tuned, can effectively predict seasonal drought events, a
737 significant limitation arises from the non-stationary relationship between the predictors and predictands used in
738 the forecasting process (AghaKouchak et al., 2022). This can limit their ability to accurately predict unprecedented
739 drought events, which fall beyond the scope of their historical training data (Hao et al., 2018). On the other hand,
740 dynamical models are proficient at capturing the nonlinear interactions among the atmosphere, land, and ocean,
741 enhancing their ability to detect the onset of droughts (Turco et al., 2017b; Ceglar et al., 2017). However, despite
742 their advanced capabilities, their forecast proficiency is generally constrained to a few months of lead time (Turco
743 et al., 2017b). To address the shortcomings associated with seasonal forecasting skills, hybrid models employ
744 statistical or machine learning methods to merge a broad variety of forecasts from statistical and dynamical models
745 into a final probabilistic prediction product (Slater et al., 2022). The frequently used merging methods include the
746 regression analysis, BMA, and Bayesian post-processing method (Hao et al., 2018; Strazzo et al., 2019; Han and
747 Singh, 2020; Xu et al., 2018). The BMA method involves the estimation of the posterior probability density
748 function (PDF) of model parameters based on the observed data and using this PDF to weight each individual
749 model forecast (Tian et al., 2023). The hybrid forecast is then generated as the weighted average of the individual
750 forecasts from statistical and dynamical models. The BMA weights estimation with simultaneous model
751 uncertainty quantification can also be used in selecting the best-performing ensemble members to reduce the cost
752 of running large ensembles (Raftery et al., 2005). There is also an opportunity to enhance the probabilistic seasonal
753 forecast skill through Bayesian post-processing methods such as the Calibration, Bridging, and Merging (CBaM)
754 technique (Schepen et al., 2014; Schepen et al., 2016; Strazzo et al., 2019). The calibration step consists in
755 optimizing the dynamical forecasts from multiple GCMs by analyzing their correlation to observed data through
756 a statistical model. In the bridging step, the dynamical forecasts from GCMs are calibrated using some large-scale
757 climate indices (e.g., ENSO, NAO, PDO, AO), and finally, the merging component combines the forecasts of the
758 two previous steps.

759 These hybrid statistical-dynamical models combine the strengths of both modeling approaches and offer several
760 advantages compared to either statistical or dynamical models alone. Thereby, seasonal drought forecasting using
761 hybrid models has recently become an active area of research (Madadgar et al., 2016; Strazzo et al., 2019;
762 AghaKouchak et al., 2022). On global scale, Yan and Wood (2013) analyzed the capability of seasonal forecasting
763 of global drought onset and found that despite climate models increasing drought detection, a significant proportion
764 of onset events are still missed. Their findings underscore the urgent need for implementing reliable, skillful
765 probabilistic forecasting methods to better manage the inherent uncertainties and potentially improve drought
766 predictability. Dutra et al. (2014) confirmed that the uncertainty in long lead time forecasts suggested that drought
767 onset might fundamentally be a stochastic problem. Mo and Lyon (2015) also found that improvements in near-
768 real-time global precipitation observations could yield the most substantial advances in global meteorological
769 drought prediction in the near term. This reinforces the notion that the effectiveness of dynamical models is
770 fundamentally associated to the quality of initial data and the inherent stochastic nature of drought onset.

771 In line with these findings, a unique approach was undertaken by Ribeiro and Pires (2016) in the MedR. They
772 proposed a hybrid scheme that combines dynamical forecasts from the UK Met Office (UKMO) operational
773 forecasting system with past observations as predictors in a statistical downscaling approach based on MLR model
774 for long-range drought forecasting in Portugal (Table 7). They concluded that hybridization improves drought
775 forecasting skills in comparison to dynamical forecasts.

776 **Table 7 Main studies using hybrid statistical-dynamical models to forecast drought in the MedR.**

777 Leveraging these advantages of hybrid statistical-dynamical models, the prediction of flash droughts has become
778 possible. Indeed, these events can develop rapidly by a quick decline in soil moisture and streamflow that may
779 cause devastating economic and ecological impacts in a short period (from a few days to 1–2 months) (Mo and
780 Lettenmaier, 2015) which makes them, particularly challenging to forecast. By providing a more nuanced
781 understanding of the drought contributing factors, hybrid statistical-dynamical models help to identify potential
782 warning signs of an imminent drought event, improve drought early warning systems, and reduce false alarm rate
783 of drought onset (Xu et al., 2018), thus tackling some of the limitations and challenges highlighted in the earlier
784 studies.

785 **7 Discussion**

786 **7.1. Drought types and indices**

787 The indices adopted by the surveyed studies were grouped according to three distinct drought categories:
788 meteorological, agricultural, and hydrological. Figure 3 illustrates the percentage of usage for each index by
789 category. Meteorological droughts were the most common, appearing in 63.00% of the examined studies, followed
790 by agricultural droughts with approximately 22.20%, whereas hydrological droughts were the least prevalent,
791 making up only 14.80%.

792 The SPI was the primary indicator, used in 70.59% of meteorological drought studies. But it also served as an
793 indicator for hydrological and agricultural droughts, with usage rates of around 25.00% and 8.33%, respectively.

794 Despite the apparent versatility of the SPI, its reliance on precipitation data limits its ability to account for other
795 influential factors such as evapotranspiration, soil moisture, land usage, and water management practices.
796 Consequently, an overemphasis on the SPI could potentially constrain our comprehension of drought phenomena
797 in the MedR. To enrich this understanding, it is recommended to incorporate a broader range of indicators and
798 models that include a more diverse set of variables. Using multivariate drought indices such as the SPEI, PDSI, or
799 sc-PDSI, or alternatively, a combination of multiple indices, can contribute to a more comprehensive view by
800 including regional feedback mechanisms in the forecast process. This approach also enhances our capacity to
801 evaluate the impacts of global warming on drought severity and intensity in the MedR (see Marcos-Garcia et al.,
802 2017; Gouveia et al., 2017).

803 **Figure 3 Pie chart showing the proportion of use of indices in the surveyed studies in MedR for different drought types.**

804 On the other hand, SDI was the most applied index in hydrological drought studies in the MedR (37.50%). It is
805 calculated by comparing the current streamflow to the long-term average or median streamflow for a specific
806 location and time of year (Nalbantis & Tsakiris, 2009). Despite its usefulness, there are some limits to using SDI
807 in MedR. Indeed, this region is known for highly variable climates with strong seasonality (wet winters and dry

808 summers) and the presence of transient streams or intermittent rivers that flow only during and after rainfall events,
809 especially in sub-humid and semi-arid areas. Groundwater recharge principally occurs during the wet season, when
810 precipitation infiltrates the soil and replenishes aquifers (Scanlon et al., 2002). In these regions, the SDI may not
811 provide an accurate representation of the hydrological drought as it relies solely on streamflow data. Therefore,
812 the use of SDI should be done in combination with other drought indices that consider variables such as
813 groundwater, soil moisture, runoff, and regional variations in precipitation and streamflow patterns for accurate
814 hydrological drought assessment.

815 One can notice from Fig. 3 that the agricultural drought studies are characterized by more diversity of indices. This
816 diversity can be explained by the varied range of agro-climatic conditions that characterize the MedR, including a
817 wide range of soil types, topography, and vegetation cover. These diverse conditions can result in varying impacts
818 of drought on agricultural production, which require different drought indices to accurately capture the extent and
819 severity of the drought. In addition, the MedR is also home to a diverse range of crops, each with different
820 sensitivities to drought (Feres & Soriano, 2007). This diversity of crops can require different indices to assess
821 the impact of drought on each crop.

822 Overall, a suitable index should be able to capture the impacts of drought, detect changes over time, and
823 differentiate between different levels of severity, while also being accurate and easily interpretable by stakeholders.

824 **7.2. Drought forecasting accuracy**

825 Key obstacles in drought modeling include the absence of a one-size-fits-all model, choosing suitable inputs,
826 determining an index that accurately represents drought tracking in various regions, and the uneven geographical
827 influence that leads to discrepancies in model accuracy (Mishra & Desai, 2005; IPCC, 2012). Consequently,
828 contrasting different methodologies is crucial for developing a reliable prediction model.

829 The accuracy of drought prediction depends on various factors such as the quality and availability of data, spatial
830 and temporal scales, prediction lead time, and model complexity, to cite but a few (Wilhite et al., 2014; Mishra &
831 Singh, 2010). For consistency, this analysis only includes studies that use R^2 as evaluation criteria of the forecast
832 with a lead time of 1 month. Joint probability models were excluded from this analysis since the accuracy
833 evaluation criteria were different. Moreover, the concept of lead time is not addressed in most of the surveyed
834 studies. It is also important to note that this analysis does not include hybrid statistical-dynamical models, as the
835 number of studies applying this approach in the MedR was quite limited. Consequently, the available research is
836 insufficient to offer a comprehensive understanding of the applicability and effectiveness of these models in the
837 region.

838 **Figure 4 Box and whiskers plot to show the performance of drought prediction models denoted by the coefficient of**
839 **determination (R^2) for the surveyed studies in MedR. The lower box shows the 25th percentile, the upper box shows the**
840 **75 percentile and the median (50th percentile) is represented by the black line inside the box. The whiskers show the**
841 **extent to the minimum and maximum values within 1.5 times the interquartile range (IQR) from the box.**

842 Figure 4 shows a box and whisker plot of drought forecasting model accuracy based on R^2 in the surveyed studies
843 in the MedR (see table1 in Appendix). According to the graph, hybrid models appear to be the most accurate and
844 consistent, with the highest median and shortest box height. Markov chains and AI models also have relatively
845 short box heights, indicating high agreement and accuracy across studies. Meanwhile, dynamical and regression

846 models exhibit moderate to high accuracy (both have median equal to 0.79), but the height of the dynamical model
847 box is shorter than that of the regression models, suggesting greater consistency. Time series models also show
848 moderate to high accuracy, with a median equal to 0.82.

849 Nonetheless, Fig. 4 provides valuable information about the relative performance of different models across
850 multiple studies in the MedR. The consistently high median of hybrid models suggests that they are particularly
851 effective for drought forecasting in the region. Similarly, the consistent performance of the AI and Markov chain
852 models, suggests that these models also show promise. The variability in the performance of the regression, and
853 the time series, as indicated by their taller boxplots, suggests that there may be more variability in the effectiveness
854 of these models across different studies and regions. The results also show that dynamical models can provide
855 valuable insights into drought conditions. However, the high variability in their performance, suggests that there
856 may be room for improvement in the development and implementation of these models in MedR.

857 This analysis concludes that simple statistical models such as Markov chains, regression, and time series can still
858 be useful in some situations and are generally more transparent and easier to interpret. For example, when focusing
859 on a single variable to forecast drought (e.g., precipitation using SPI), simple models like ARIMA can effectively
860 capture the temporal patterns and provide reasonable forecasts. Or, when drought conditions can be effectively
861 represented by discrete states or categories, Markov chains can be employed to model the transition probabilities
862 between these states and forecast future drought conditions (Habibi et al., 2018; Nalbantis and Tsakiris, 2009;
863 Paulo and Pereira, 2007). Also, when working with a limited number of variables and moderate interactions,
864 simple regression models like linear or logistic regression can provide adequate predictions of drought conditions
865 (Sharma et al., 2017). The effectiveness of simple models in these situations depends on the specific context and
866 the data quality and quantity. When more complex relationships or high-dimensional data are involved, it may be
867 necessary to employ more advanced models like dynamical models or combine simple models with techniques
868 like machine learning, copulas, or hybrid approaches to improve forecasting performance. Hybrid statistical-
869 dynamical models present a promising avenue for enhancing forecast accuracy, particularly for extended lead
870 times and in situations where intricate processes and interactions are critical (AghaKouchak et al., 2021; Mehran
871 et al., 2020; Madadgar et al., 2016). The relatively nascent emergence of these hybrid techniques has resulted in a
872 limited number of studies applying them in the MedR. This can be ascribed to factors such as data constraints,
873 computational complexity, and model uncertainty. Moreover, proficiency in both statistical and dynamical
874 modeling is needed, and interdisciplinary cooperation is frequently deficient. Notwithstanding these challenges,
875 there is an increasing interest not only in enhancing traditional dynamical models but also in the development and
876 utilization of hybrid models. As research progresses and resources become more accessible, these hybrid models
877 may see wider adoption for their potential to improve predictive accuracy.

878 **7.3. Spatial and Temporal Scales of Drought**

879 Figure 5 displays the spatial and temporal scales of drought forecasting studies in the MedR with a pie chart
880 indicating the percentage of use of drought forecasting method: statistical, dynamical, and hybrid statistical models
881 for each spatiotemporal scale. This figure shows that the number of droughts forecasting studies tends to decrease
882 as the spatial scale increases and increases as the time scale increases. We can also notice from this figure that the
883 majority of studies in the MedR focused on the local scales (e.g., city or catchment), particularly at annual and

884 seasonal time scales. In contrast, very few studies were conducted at the MedR scale, and only a few studies were
885 conducted at the country scale.

886 **Figure 5 Spatial and temporal scales of drought forecasting studies in the Mediterranean region with a pie chart**
887 **indicating the percentage of use of drought forecasting method: statistical, dynamical, and hybrid statistical models for**
888 **each spatiotemporal scale.**

889 When considering the spatial scale, drought forecasting becomes more challenging at larger scales due to various
890 factors. One of the major challenges is the complexity of the interactions between different factors that contribute
891 to droughts, such as precipitation, temperature, soil moisture, and vegetation cover (Sheffield & Wood, 2011).
892 These interactions are nonlinear and difficult to capture accurately, especially at larger scales where there are more
893 variability and heterogeneity (AghaKouchak et al., 2015). For instance, at the country scale, there could be
894 different microclimates, topography, and land use practices that affect these factors differently (Vicente-Serrano
895 et al., 2010a). This heterogeneity tends to increase as the spatial scale increases, making it harder to calibrate and
896 validate drought forecasting models. On the other hand, the small number of studies that focused on large
897 geographic areas is probably due to the challenge of data availability and homogeneity, which arises due to
898 limitations in data collection and standardization, particularly at larger spatial scales (Dai, 2011). This can lead to
899 incomplete or inconsistent datasets, which in turn can impact the accuracy of drought forecasting models. Remote
900 sensing technologies can provide a solution to this problem by allowing for the collection of large-scale, high-
901 resolution data that can improve the accuracy of forecasting models (Gouveia et al., 2017). The role of remote
902 sensing data in improving drought prediction will be further discussed in sect. 8.2.

903 When considering the time scale, the number of droughts forecasting studies tends to increase as the scale
904 increases. Drought research often emphasizes seasonal, annual, or decadal scales due to various factors. The slow-
905 onset nature of droughts necessitates studying their progression and recovery over extended periods (Mishra &
906 Singh, 2010). Investigating longer time scales also allows researchers to analyze the impact of large-scale climate
907 drivers, such as ENSO or NAO, on drought events (Dai, 2011). Moreover, focusing on these time scales enables
908 a better assessment of drought consequences on water resources, agriculture, and ecosystems, which are more
909 pronounced over extended periods (Wilhite & Pulwarty, 2017). Additionally, data availability and reliability tend
910 to be higher for longer time scales, facilitating more robust analyses. Long-term trends and climate change impacts
911 on droughts can also be better understood at longer time scales (Trenberth et al., 2014).

912 Notably, only one study focused on the weekly time scale. Drought forecasting at small scales or weekly time
913 scales offers several advantages, including early warning and improved water management (Pulwarty &
914 Sivakumar, 2014), quick response to flash droughts (Mo & Lettenmaier, 2015), support for agricultural decision-
915 making (Hansen et al., 2011), improved accuracy of longer-term forecasts (Yuan et al., 2015), and model
916 improvement and validation (Wood et al., 2016). However, drought forecasting at such a small scale may be more
917 challenging due to the chaotic nature of the atmosphere, making it difficult to accurately model complex
918 interactions between atmospheric conditions, land surface characteristics, and water management practices over
919 short periods (Lorenz, 1963; Seneviratne et al., 2012).

920 On the other hand, the most commonly used forecasting methods were statistical and hybrid statistical models,
921 with only a few studies applying dynamical models and the percentage of studies applying this last approach
922 increases with an increase in the temporal scale. There could be several reasons for these findings. Dynamical

923 models require large amounts of high-quality input data, which may not be readily available for the MedR due to
924 limitations in historical data and spatial coverage (Giorgi & Lionello, 2008). Statistical and hybrid statistical
925 models often have lower data requirements and are generally computationally more efficient than dynamical
926 models, making them more suitable for regions with limited data availability and computational constraints.
927 Furthermore, the percentage of studies applying dynamical models increases with an increase in the temporal scale
928 because these models are better suited for capturing long-term climate variability and the influence of large-scale
929 climate drivers (Dai, 2011; Sheffield et al., 2012). Statistical and hybrid statistical models, conversely, are more
930 effective at capturing short-term variability and local-scale processes, which are often more relevant for drought
931 forecasting in the MedR (Mehran et al., 2014). Lastly, data availability at shorter temporal scales can be a limiting
932 factor for developing and validating dynamical models (Shah et al., 2018).

933 In summary, while increasing the spatial scale can decrease the accuracy of drought forecasting studies, increasing
934 the time scale can improve the accuracy by allowing for a more comprehensive understanding of the various factors
935 that contribute to drought conditions. It is essential to consider both spatial and temporal scales when conducting
936 drought forecasting studies to ensure the most accurate predictions possible.

937 **8 Challenges and Future Prospects**

938 In the earlier discussion, we analyzed drought indices, factors affecting the accuracy of drought forecasts, and the
939 significance of spatial and temporal scales in drought predictions within the MedR context. Building on this
940 understanding, the following sections will focus on the challenges and prospects within the realm of drought
941 forecasting, which will help to pinpoint potential avenues for progress and innovation in this area.

942 **8.1. Data Assimilation**

943 The lack of in-situ measurement networks and coarse global seasonal forecast skills
944 has hindered drought forecasting facilities, especially in data-poor regions (Pozzi et al.,
945 2013; Haile et al. 2020). In this regard, Data Assimilation (DA) provides a powerful approach to enhancing drought
946 forecasting accuracy by incorporating different observations and climate forecasts into a hydrologic model to
947 generate more precise initial conditions (Hao et al., 2018; Tang et al., 2016). Therefore, many studies have referred
948 to this method to better forecast hydroclimatic variables (e.g., Bazrkar and Chu, 2021; Peng, 2021; Xu et al., 2020;
949 Liu et al., 2019; Steiger et al., 2018; Steiger and Smerdon, 2017). The ensemble Kalman Filter (EnKF) (Evensen,
950 1994) algorithm is one of the most popular DA techniques applied by the hydrologic community. However, this
951 assimilation method is subject to some inherent drawbacks especially in nonlinear dynamic systems thus resulting
952 in suboptimal performance and violation of water balance (Abbaszadeh et al., 2018). Given these limitations,
953 emphasis should be placed on the development of improved DA algorithms better adapted to hydrologic models,
954 which allow the modeling of different temporal and spatial scales and the improvement of water balance. This can
955 be achieved by modifying the standard approaches such as the ensemble Kalman filter or variational algorithms
956 so that, accurate predictions can be obtained at a reasonable computational cost. These include among others hybrid
957 EnKF-Var methods (Bannister, 2017; Bergou et al., 2016; Mandel et al., 2016) and AI algorithms for ensemble
958 post-processing (Grönquist et al., 2021). One recent advance in data assimilation techniques for drought
959 forecasting is the use of machine learning algorithms to improve the accuracy of predictions. For example,
960 researchers have used machine learning techniques to develop models that can analyze large amounts of data from

961 a variety of sources and generate more accurate forecasts of drought conditions (Aghelpour et al., 2020; Rhee and
962 Im, 2017; Feng et al., 2019). These models can also be updated in real time as new data becomes available,
963 allowing for more accurate and up-to-date forecasts. Another advance in data assimilation techniques for drought
964 forecasting is the use of remote sensing data and reanalysis to improve the accuracy of predictions, which may be
965 particularly beneficial in areas where ground-based observations are limited (Shahzaman et al., 2021b; Shi et al.,
966 2011).

967 **8.2. Remote Sensing and Reanalysis**

968 Various challenges in drought modeling in the MedR are related to data availability. The lack of climatic and
969 hydrological observations in ungauged catchments, low station density, short data records, data gaps, and limited
970 data access in some Mediterranean countries. All these challenges can limit the accuracy and reliability of drought
971 predictions. Although many efforts are being deployed by developing new complete datasets in the MEDR (Tuel
972 and El Moçayd, 2023), finding alternative data sources and modeling techniques is essential to tackle these
973 challenges.

974 Remote sensing data can provide real-time information about the Earth's surface facilitating effective drought
975 forecasting, monitoring, and early warning (Zhang et al., 2016). Agricultural drought can be assessed by analyzing
976 changes in vegetation cover over time. Indeed, drought can lead to marked changes in the health and vigor of
977 vegetation, and these changes can be detected using remote sensing data (Belal et al., 2014). By analyzing changes
978 in vegetation greenness over time, it is possible to identify areas that are experiencing or are at risk of experiencing
979 drought stress. Moreover, drought conditions related to vegetation or evapotranspiration can also be monitored
980 with drought indices from remote sensing products, such as NDVI or Evaporation Stress Index (ESI) (Shahzaman
981 et al., 2021a). Microwave satellite data can also be used to estimate soil moisture levels during crop growing
982 season, which can be used to predict and monitor potential agricultural droughts (Le Page and Zribi, 2019; Yuan
983 et al., 2015).

984 In addition, satellite observations of precipitation and soil moisture such as IMERG (Huffman et al., 2015),
985 PERSIANN-CCS (Sadeghi et al., 2021), CHIRPS (Funk et al., 2015), SMAP (Entekhabi et al., 2010), MSWEP
986 V2 (Beck et al., 2019), GLEAM v3 (Martens et al., 2017), and DROP (Turco et al., 2020) can be used in
987 conjunction with the in-situ observations and ground-based radar observations data to fill observational gaps.

988 Moreover, data from numerical weather forecasting reanalysis such as ERA5-land were used instead or along with
989 direct observations to forecast drought in many studies (Babre et al., 2020; Junqueira et al., 2022; Parker et al.,
990 2021). ERA5-land is a state-of-the-art global reanalysis dataset that can provide a consistent view of the evolution
991 of land variables (e.g., precipitation, temperature) over several decades at an enhanced resolution (~10 km). This
992 product obtained by assimilating observations through a 4D-VAR data assimilation technique can be used as
993 ground truth in data-poor regions. For example, ERA5-land can be used to calibrate and validate climate forecasts
994 and to choose an ensemble of the most skilled GCMs in reproducing the actual observed climate in a specific
995 region.

996 Similarly, SAFRAN, a high-resolution meteorological reanalysis, has shown its utility in regions with sparse
997 observational data. Trambly et al. (2019) used SAFRAN to generate a high-resolution (5 km) gridded daily
998 precipitation datasets for Tunisia between 1979 and 2015. Their study, which combined data from 960 rain gauges

999 with the SAFRAN analysis, demonstrated that SAFRAN surpassed other standard interpolation methods like
1000 Inverse Distance, Nearest Neighbors, Ordinary Kriging, or Residual Kriging with altitude. The outcome was a
1001 highly accurate gridded precipitation dataset that could be instrumental for climate studies, model evaluation, and
1002 hydrological modeling to support the planning and management of surface water resources.

1003 Finally, remote sensing data and reanalysis remain valuable tools for drought forecasting and monitoring, as it
1004 provides timely land surface information that can fill the observational gaps, help to identify areas at risk of
1005 potential drought conditions and to monitor the progression of drought over time.

1006 **8.3. Uncertainty analysis in drought forecasting**

1007 In spite of the large number of studies that have been carried out on the probabilistic characterization of drought,
1008 the quantification of uncertainty of these forecasts is still ignored in major studies. Uncertainty analysis is an
1009 important aspect of probabilistic drought forecast, as it allows users to understand the degree of confidence
1010 associated with the forecasted probabilities (Hao et al., 2016; Dehghani et al., 2014). Therefore, more efforts
1011 should focus on quantifying the uncertainty beyond just an ensemble of model simulations (AghaKouchak et al.,
1012 2022).

1013 Drought forecasting is subject to epistemic and aleatory uncertainties. The first one arises from incomplete
1014 knowledge of drought processes and can be reduced with improved understanding, more data, and good models'
1015 calibration and validation. The second one is related to the inherent variability and randomness in natural systems
1016 and is often difficult to reduce (Pappenberger & Beven, 2006). In addition, uncertainties in drought forecasting
1017 can vary by region, spatial scale, and temporal scale. As we discussed in sect. 7.3, even well calibrated and
1018 validated, the drought forecasting model will not necessarily perform equally well in all periods or locations. By
1019 considering the uncertainty of the drought model as a nonstationary process in space and time, researchers can
1020 gain new insights into the variability of uncertainty and its underlying causes (AghaKouchak et al., 2022). This
1021 perspective can help identify regions or periods where the uncertainties are particularly high, which can guide
1022 further research, data collection, and model development efforts. Additionally, understanding the space-time
1023 variability of uncertainty can inform the development of more robust and reliable forecasting and decision-making
1024 approaches that account for the changing nature of uncertainty.

1025 Various techniques can be employed to quantify drought forecast uncertainty, including ensemble forecasting
1026 (Palmer et al., 2004), Bayesian methods (Vrugt et al., 2008), sensitivity analysis (Saltelli et al., 2008) and
1027 probabilistic forecasting (Gneiting et al., 2005). Probabilistic drought prediction can also involve the use of data
1028 assimilation techniques to integrate different data sources, including remote sensing data, ground-based
1029 observations, and output from meteorological and hydrological models. Lately, hybrid statistical-dynamical
1030 models have shown their potential in reducing uncertainties associated with both statistical and dynamical methods
1031 (Yuan et al., 2015; Madadgar et al., 2016). For example, shortcomings in dynamical model physics or data can be
1032 counterbalanced by the empirical associations in statistical models. While, uncertainties in statistical models
1033 resulting from shifting climate conditions can be tackled by the physically based dynamical models (Yuan et al.,
1034 2015).

1035 In summary, probabilistic drought prediction with uncertainty analysis can be useful tools for decision makers, as
1036 they provide a more comprehensive view of the potential impacts of drought and allow for more informed risk

1037 management decisions. However, what is missing in the current drought forecasting models is not just the
1038 uncertainty quantification, but also a lack of awareness of it (AghaKouchak et al., 2022).

1039 **8.4. Drought Information Systems**

1040 A critical component of proactive approaches to drought preparedness is providing timely and
1041 reliable climate information, including seasonal forecasts, that helps decision makers prepare
1042 management policies (Manatsa et al., 2017). Identifying drought risk timely depends on our
1043 ability to monitor and forecast its physical causing mechanisms at the relevant spatiotemporal
1044 scale. An integrated national drought monitoring and early warning system has been
1045 implemented in many regions and countries such as the United States, New Zealand, South Asia, India, and Europe
1046 (Prabhakar and Rama, 2022) but has not taken place until recently in developing countries (e.g., the Southern and
1047 Eastern Mediterranean countries). This is probably due to the lack of a drought information system, the sparse
1048 observation networks, and the low predictability of seasonal precipitation in these countries. To overcome these
1049 limitations, there is a need for developing a Drought Information System with a complete approach allowing data
1050 collection and preprocessing, accurate probabilistic drought risk prediction using a combination of ensemble
1051 climate seasonal forecasts, ground-based observations, reanalysis, conventional and remote-sensing observations,
1052 artificial intelligence, data assimilation and hydrological models and drought information dissemination through a
1053 web-based Drought Early Warning System (DEWS).

1054 **9 Conclusions**

1055 This study reviewed the recent statistical, dynamical, and hybrid statistical-dynamical methods used to forecast
1056 droughts and their application on the MedR. Drought definitions, classification, indices, and causative physical
1057 mechanisms were also presented in the context of the MedR. The main conclusions of this review are:

- 1058 1. There are only a few studies on the analysis of physical mechanisms causing droughts in the MedR. The
1059 review of these studies confirmed that seasonal drought predictability skills are still very limited over the
1060 region due to its relatively poor teleconnection with ENSO compared to the tropical and subtropical regions.
1061 Besides, MedR is strongly influenced by other climate patterns, such as the NAO, regional MO, ULMOi,
1062 and NAWA which can also affect the region's weather and climate but their relationship to drought onset
1063 is rather weak and could not explain major droughts in the region. Land surface memory can also contribute
1064 to the predictability of seasonal and sub-seasonal droughts. Thereby, an accurate representation of these
1065 land-atmosphere processes is needed to improve drought forecasting skills in mid-latitude regions such as
1066 the Mediterranean.
- 1067 2. Statistical models were largely used to forecast droughts in the MedR. One of the major limitations of these
1068 models is that they often assume a stationary relationship between the predictors and the predictands which
1069 can lead to potentially inaccurate forecasts. In this regard, AI models such as SVR, SVM, and ANN have
1070 proven good capacity in detecting local discontinuities and non-stationary characteristics of the data and
1071 show satisfactory forecasting skills at less than 6 months lead time. Moreover, sophisticated statistical
1072 models, incorporating a data pre-processing technique such as wavelet analysis, EMD, or PCA with AI
1073 models have proven to be more efficient than using a single model and can extend the lead time of the
1074 drought forecast up to 12 months. The copulas can also provide valuable insights into the complex

1075 relationships between different drought predictors. The use of copulas enables a more in-depth analysis of
1076 the nonlinear dependencies between variables such as temperature, precipitation, and soil moisture, yielding
1077 a more comprehensive understanding of the factors that contribute to drought risk in a specific region. This
1078 leads to a more sophisticated and reliable forecast of drought probability. Thus, copulas are a highly useful
1079 resource in the ongoing effort to understand and manage the consequences of drought.

- 1080 3. Dynamical models, given their ability to capture nonlinear interactions across the atmosphere, land,
1081 and ocean, offer considerable potential for more accurate and reliable seasonal drought predictions.
1082 However, the inherent chaotic nature of the atmosphere restricts their forecast skill to a few months in
1083 advance. The dynamical drought forecasting has seen notable advancements, such as enhanced climate
1084 model resolution, refined representation of physical processes, improved initialization methods, the
1085 application of multi-model ensembles, and the development of coupled modeling approaches. These
1086 developments have indeed bolstered the accuracy and reliability of drought predictions. Nevertheless,
1087 the implementation of these models in the MedR is constrained by challenges such as limited data
1088 availability, computational complexity, and inherent model uncertainties.
- 1089 4. Hybrid statistical-dynamical models can be promising tools to potentially enhance the accuracy and
1090 reliability of drought forecasting in the MedR. By merging a broad variety of forecasts from statistical and
1091 dynamical models into a final probabilistic prediction, hybrid models benefit from the strengths of both
1092 modeling approaches and improve the forecast skill compared to an individual model. But their
1093 applicability remains challenging due to several constraints. Indeed, the hybrid model may require careful
1094 calibration and validation to ensure that they are performing optimally which can be time-consuming,
1095 requiring a large amount of data, specialized expertise, and high computational resources.
- 1096 5. One of the major challenges in drought forecasting in the MedR is the lack of long-term, high-quality
1097 hydroclimatic observations to convey the nonstationary patterns and the variability of the climate. In
1098 addition, hydrologic model predictions are often poor, due to model initialization, parametrization, and
1099 physical errors. To address these challenges, it is important to improve the availability and quality of data
1100 for drought forecasting in this region. This could involve implementing better monitoring systems and
1101 increasing the number of weather stations in the region. In addition, efforts should be made to improve the
1102 performance of drought forecasting models by using more advanced data assimilation and machine learning
1103 techniques and to incorporate data from other sources such as state-of-art satellite observations and
1104 reanalysis with relatively high spatiotemporal analysis to provide a superior hydrologic and climate states
1105 estimate and consequently a skillful agricultural and hydrological drought forecasting.
- 1106 6. Drought mapping is the final stage in which drought risk information is disseminated and communicated
1107 to end users. Major studies in the MedR analyze drought risk using some drought indices without applying
1108 a visualization via maps or presenting the risk on a single map showing the overall risk situation. An
1109 informative visualization of results via probabilistic drought risk maps is recommended, whereby color
1110 gradations or contouring are used to effectively illustrate the range of probabilities. Ensuring cartographic
1111 rigor, such maps should maintain spatial accuracy, use appropriate scaling, and include a clearly defined
1112 legend to decrypt different probability levels. Uncertainties related to drought modeling and prediction also
1113 need to be perspicuously defined, discussed and communicated to increase the intelligibility and
1114 comprehensibility of decision makers, farmers, and other end users.

1115 7. Finally, much effort should be done to improve the communication and dissemination of drought forecasts
 1116 which can help in extending their lead time by ensuring that decision makers and stakeholders have access
 1117 to the most up-to-date information.
