27 **Prediction of landslide induced debris' severity using machine learning**
28 **algorithms: a case of South Korea**

29 **Abstract**

30 Rainfall-induced landslides frequently occur in the mountainous region of Korean peninsula.
31 The resulting landslide induced debris cause extreme property damages, huge financial losses
32 and human deaths. To mitigate their effect different landslide susceptibility mapping are
33 frequently used. However, these methods do identify regions with potential landslides but they
34 do not quantify their severity. In this paper multi-category ordered machine models, namely,
35 proportional odd logistic regression (POLR), random forest (RF), support vector machine
36 (SVM), and extreme gradient boosting (EGB) methods, are proposed to fill the specified gap.
37 Moreover, the exploratory data analysis on landslide induced debris's dataset has been
38 conducted on to examine patterns and relationship between landslide-induced debris
39 severity(size), causal factors(rainfall) and influencing factors. Findings revealed that
40 cumulative three days' rainfall and slope length were most responsible for the severity of
41 landslide-originated debris severity and slopes between 20° to 40° was identified as most
42 vulnerable region. Furthermore, the predictive accuracy statistics were compared to assess the
43 suitable model for debris severity for Korean case. The RF and EGB ranked higher with an
44 overall accuracy of 90.07% and 86.09% and kappa of 0.72 and 0.61 on the validation set,
45 respectively. The findings of this research may be useful in the identification of high risk zones
46 for extreme rainfall-induced debris to elaborate mitigation and resilience policies, post-disaster
47 rehabilitation planning and land use management.

50 forest; Support vector machine; Extreme gradient boosting; Machine learning , South Korea

51 **1. Introduction**

52 Rainfall-induced debris is a natural phenomenon that occurs when the slope fails due to the
53 saturation of soil after the rainfall exceeds a certain threshold (Au 1998; Takara et al. 2010;
54 Peruccacci et al. 2017; Segoni et al. 2018; Crawford et al. 2019; Coppola et al. 2022).
55 Rainwater penetrates the soil through cracks or pores (Zeng et al. 2022) which destabilizes the
56 slope and induces landslides (Franzluebbers 2002). Furthermore, the volume of landslide-
57 induced debris depends on the geological condition of the terrain, rainfall intensity and duration
58 (Chang et al. 2011). Extreme rainfall is the triggering factor for landslides which is one of the
59 most damaging natural disasters with the expensive cost of repair and indemnification
60 (Kockelman 1986; Gariano and Guzzetti 2016). In addition, heavy windstorms, typhoons, and
61 extensive rainfall have destroyed many properties and taken many human lives yearly (Liu et
62 al. 2018). Furthermore, landslides have caused enormous environmental degradation,
63 infrastructure damage, casualties, and loss of life, which disturb the socio-economic aspect of
64 the community (Li et al. 2012; Sarkar and Dorji 2019; Zhao et al. 2019; Taylor et al. 2020;
65 Lacroix et al. 2020; Winter 2020; Negi et al. 2020; Ju et al. 2020; Van et al. 2021). Most rainfall-
66 induced landslides were found to be shallow (de Jesús et al. 2019; Liu et al. 2021; Chang et al.
67 2021) however, some were very extreme and resulted in severe human and financial damage
68 (Turner, 2018; Meena et al., 2021). Klose et al. (2016) found that from 1980 to 2013, landslides
69 took thousands of lives and an annual average of about \$20 billion of economic losses, which
70 was 17% of the total (\$121 billion) annual mean of global disaster-induced losses.

71 The Korean peninsula is characterized by mountainous, which makes it more prone to
72 rainfall-induced landslides (Lee et al. 2013). Lee et al. (2012) found that the triggering factor
73 for landslides was short-duration heavy rainfall. Park et al. (2013) reported that the annual
74 property damage caused by rainfall-induced landslides in South Korea averaged between
75 US\$500M to US\$1000M and approximately 36 human deaths per year from 1997 to 2010.

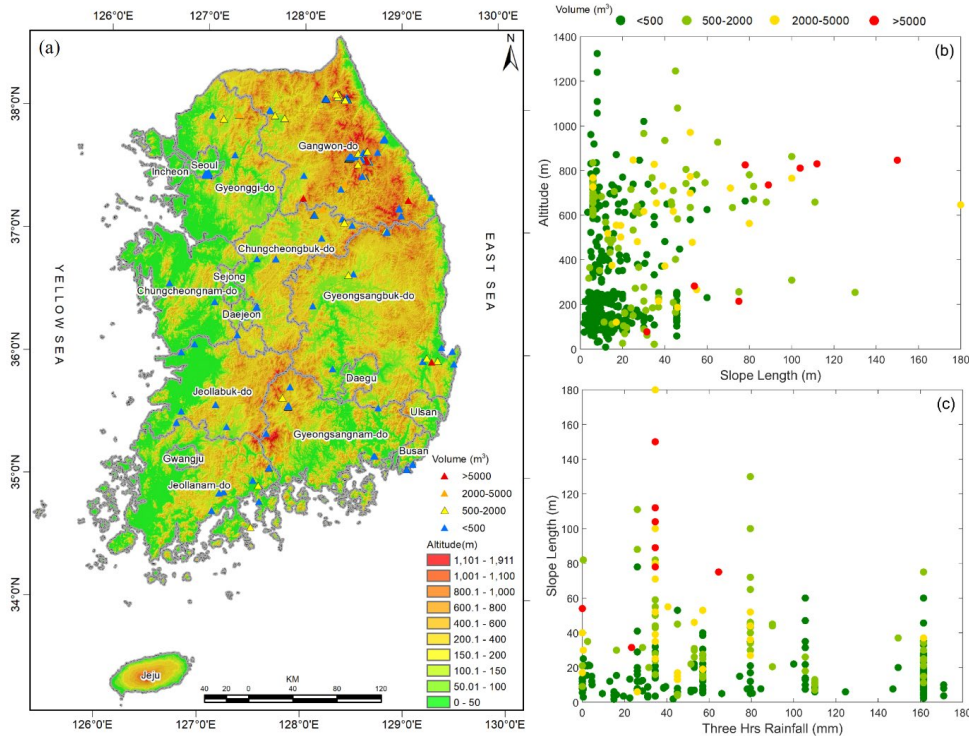

76 Therefore, to mitigate the effect of landslides in South Korea, different studies have been
77 carried out on landslide assessment (Kadavi et al. 2019; Lee and Winter 2019; Sameen et al.
78 2020; Panahi et al. 2020; Hakim et al. 2022). Lee et al. (2020) applied the Naïve and Bayesian
79 Networks model for landslide susceptibility mapping in Umyeon Mountain. Lee et al. (2012)
80 used physical slope and probabilistic model, i.e., decision trees and logistic regression for
81 landslide susceptibility mapping in Gangwon-do. Lee et al. (2013) developed the binary
82 logistic regression model for predicting the occurrence of landslides. Woo et al. (2014)
83 constructed a landslide hazard map using binary logistic regression. Park and Kim (2019)
84 compared boosted trees and random forest model's performance in landslide susceptibility
85 mapping for Umyeon Mountain; the same methods were previously applied at Pyeong-Chang
86 by Kim et al. (2018). It was observed that the objectives of previous studies were to predict
87 landslide susceptibility; they did not specify how severe the occurring landslides would be.
88 Further, most of studies were performed on a small scale and only predicted the occurrence,
89 not the size. Therefore, in the present study, we analyzed landslide-induced debris severity
90 based on the causative variables and influencing factors. This study is novel in expressing the
91 relationship of debris' severity, causative and influencing factors. It is an extension on landslide
92 mapping which quantifies the magnitude of landslide-induced debris. The quantification of
93 debris severity may be useful in land management by highlighting regions prone to higher
94 rainfall-induced debris to know whether economic activities that may be carried out on the
95 given region may not be vulnerable to extreme landslide hazards. The severity of debris is
96 measured in unit of volume (m^3) and classified as shallow(below $500m^3$), small($500-2000m^3$),
97 medium ($2000-5000m^3$) and critical, i.e., above $5000m^3$. Words severity of debris, debris
98 volume or size of debris express the same quantity in different ways and are used
99 interchangeably in this manuscript.

100 **2. Study region**

101 Korean peninsula is located in the northern hemisphere, between China and Japan in Northeast
102 Asia. Its climate has continental and oceanic features with wide temperature differences. The
103 yearly mean temperature ranges from 10°C to 16°C, that is, from -6°C to 7°C in winter and
104 23°C to 27°C in summer. In South Korea, the rainy season range from June to September, with
105 1000mm to 1800mm of precipitation in the southern part and 1100 to 1400mm in the central
106 region (<https://web.kma.go.kr/>).

107 The altitude ranges from 0 to 1911 meters, with mount Halla (in Jeju Island) being the
108 highest peak in South Korea. The Gangwon Province is the most mountainous region of about
109 64% of all tallest mountains in Korea, that is, 23 of 36 mountains. The surface geology of the
110 Korean peninsula is mostly composed of igneous, sedimentary, and metamorphic rock (Chough
111 et al., 2000). The arable soil depth varies between 1 to 2m (Lee and Winter, 2019). Due to the
112 high intensity rainfall and weak geological formation in the mountainous region causes high
113 frequency of landslides. Figure 1(a) illustrates the distribution of landslides by the volume of
114 landslides, while subplots (b & c) exhibited the relationship of slope length, altitude, and
115 rainfall with the landslide size.

116

117 Figure 1. (a) Landslide location in South Korea, (b) Distribution of landslide volume per
118 slope length and altitude, and (c) Distribution of landslide volume per slope length
119 and rainfall (Data source: elevation data acquired from NGII, 2018).

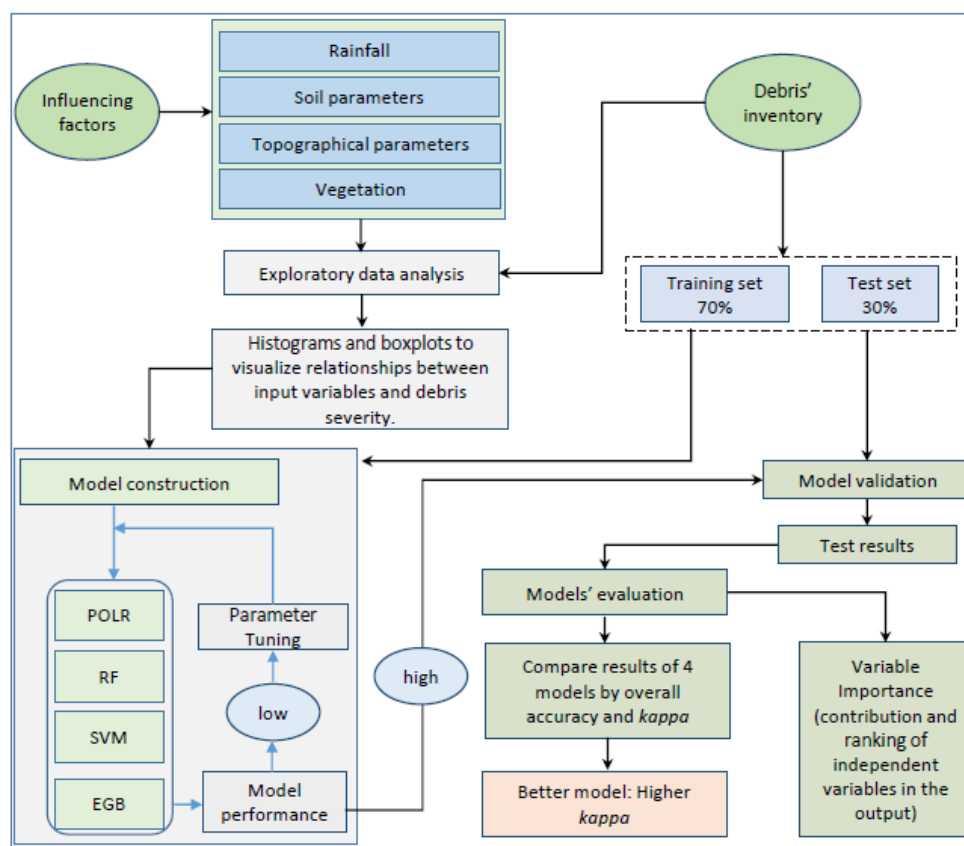

120 3. Methodology

121 3.1. Problem formulation

122 Predictive models that deal with multi-variate random variables were investigated to
123 predict the severity of rainfall-induced landslides. Among those predictive models,
124 proportional odd logistic regression and other machine learning-based algorithms such as
125 extreme gradient boosting, random forest, and support vector machine are widely used to deal
126 with classification problems (Marjanović et al. 2011; Lee et al. 2012; Woo et al. 2014; Wang et
127 al. 2022a). The main steps for the modeling process were to analyze the interaction of variables

128 that influence the severity of landslides with results in a higher size of debris. For the purposes,
129 four machine learning models i.e., POLR, RF, SVM, and EGB, were used to assess the most
130 suitable predictive model for landslide-induced debris in south Korea (;Su et al.,2022). The
131 comparison was made using predictive accuracy and the value of *kappa*. Figure 2 shows the
132 steps followed in the construction of the model.

133
134 **Figure 2.** Modelling workflow process for the prediction of landslide induced debris' severity
135 using machine learning algorithms.

136 3.2. Data description

137 The dataset contains 455 debris inventory collected from field surveys with the help of

138 portable GPS, a laser ranger and a clinometer. Variable definitions and descriptions for each
139 feature in the dataset are presented in Table 1. The rainfall data were collected from Korea
140 meteorological Administration stations scattered around the country nearest each landslide-
141 induced debris site. It was revealed that the duration and quantity of rainfall directly affect
142 landslides (Berti et al. 2012; Kim et al. 2014; Sarkar et al. 2019; Liu et al. 2020; Ngo et al.
143 2021). Rainfall data were grouped into twelve variables: cumulative rainfall, continuous hourly
144 rainfall, three hours, six hours, nine hours, twelve hours, one day, three days, seven days, two
145 weeks, three weeks, and four weeks' rainfall. Different measures of rainfall were captured due
146 to the time-dependent cumulative effect of rainfall on the slope stability, and prolonged rainfall
147 has a more damaging effect in mountainous regions (Baum and Godt 2010; Hidalgo et al. 2017;
148 Meena et al. 2022). The conditioning factors, i.e., soil type, topsoil depth, altitude, slope, slope-
149 length, slope aspect, and vegetation (leafage, size of tree, age of trees, and fire history), were
150 collected. The soil type was classified as sandy loam, lithosols, silt loam, and clay. The soil
151 depth was grouped into below 20 centimeters, between 20-50, and 50-100 centimeters. The
152 rainfall infiltrating the topsoil causes saturation, which initiates the landslide and then results
153 in debris flow (Baum and Godt 2010;Vahedifard et al., 2017; Zhu and Zhang 2019). The anti-
154 erosive drainage presence and status were categorized into: very good, good, and bad. Drainage
155 channels reduces the concentration of water in soil and effect on water flow, saturation, soil
156 moisture, and valley landslides(Shahabi and Hashim 2015). The vegetation-covered and
157 necked lands have different affect of landslide (Lee et al. 2013; Ozioko and Igwe 2020;Huang
158 et al. 2021). The foliage information was classified into pines, broad-leaved, and mixture, while,
159 the size of trees was classified as large, small, and medium. The age of trees was grouped into
160 seven classes viz. 1-5 5-15, 15-25, 25-35, 35-45 and >45 years. The forest fire history was also
161 considered as a influencing factor due to its erosive nature(Huang et al. 2020). Geographical
162 features were found to contribute to the severity of landslides at different levels; steep slopes

163 were found to fail as the intensity of the rainfall increased (Brand et al. 1984; Au 1998; Charles
164 and Shi 1998; Nandi and Shakoor 2008; Pham et al. 2018; Chen et al. 2020). It was also noted
165 that plane areas beneath steep slopes face the damage caused by debris flowing from the top of
166 mountains (Raja et al. 2017, Wang et al. 2022b).

167

168 The output variable (volume) of landslides has been classified into four categories, i.e.,
169 below 500m^3 , between $500\text{-}2000\text{m}^3$, $2000\text{-}5000\text{m}^3$, and above 5000m^3 (Fig. 4c). There are
170 different types of landslides; which are classified based on the cause or shape after occurrence
171 (Causes 2001). Landslides may result from liquefaction, earthquakes, intense surface water
172 flow due to precipitation, underground water, ice melting, human activities, tectonic
173 movements etc.(Alexander 1992; Causes, 2001; van der Beek, 2021;McColl 2022). In this
174 paper, we only considered landslide-induced debris originating from rainfall. Table 1
175 summarizes the characteristics of debris: its types, frequency and size.

176 Table 1: Landslide-induced debris types and frequency

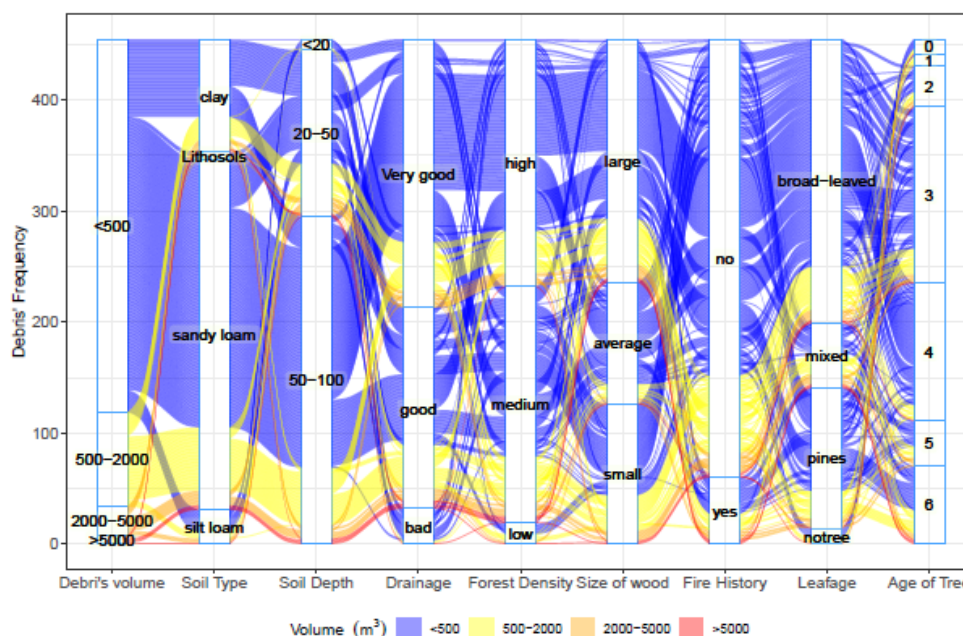

Destroyed area \ Volume (m^3)	<500	500-2000	2000-5000	>5000	Total
valley erosion	1	1	1		3
falling rocks	1				1
mixed/ complexes	3	2	1		6
slope	1	1		1	3
scour	1				1
curved wedges	4	1			5
a circular arc	205	45	14	2	266
Plane	120	35	10	5	170
Total	336	85	26	8	455

177 3.3 Exploratory data analysis

178 The relationship between the influencing factors and the debris size were analyzed. We
179 consider categorical variables, also known as qualitative set of information, that is divided into
180 groups. It describes data which are non-numerical and serve qualitative purposes, such as

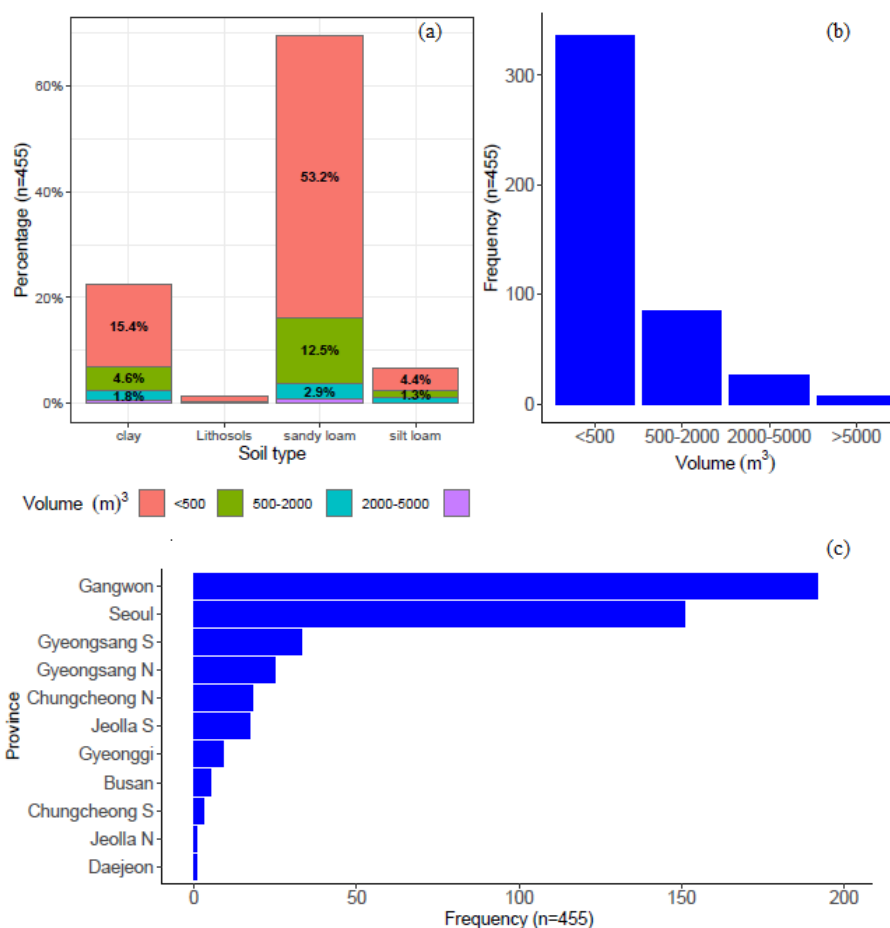

181 representing a certain value or distinctive character of objects (nominal), when there is no order
182 in levels and ordinal when there is an order in the dataset (Bilder and Loughin 2014). In addition,
183 continuous features were presented in form of histograms and boxplots to analyze the
184 dispersion and influence on the size of debris. Figure 3 illustrates that most of the occurred
185 debris was shallow (below 500m³, 73.85%), followed by 500-2000m³ (18.68%), and the
186 extreme debris (above 5000m³) was the least frequent (1.76%). Debris with a size above
187 5000m³ was mainly associated with sandy loam soil of depth above 20cm and a non-perfected
188 drainage system, where the forest density was medium and in a place that experienced wildfire.
189 The region with pines leafage experienced shallower debris compared to other types of leafage.
190 The region with older trees, above 45 years of age, experienced more severe debris than
191 younger forests. Šilhán and Stoffel (2015) highlighted that the area with timber age of above
192 45years were more sensitivity to landslide occurrences. The size of debris for wildfire-
193 experienced regions was observable; compared to the frequency of cases with no wildfire
194 history, the severity was quite higher. The wildfire influence on the rainfall-induced debris is
195 due to the reduced infiltration of water into the soil, which increases the erodibility of soil
196 (Ranger et al. 2020; Tiwari et al. 2020). The inadequate drainage system resulted in severe
197 debris(Popescu 2002), where the system was very good, no severe debris occurred. The
198 resulting huge number of shallow debris for a very good drainage system is due to the fact
199 those systems are usually created in the most vulnerable regions and the shallow debris is an
200 indication of improvement in landslide mitigation.

201

202 Figure 3. Interlinkage between the size of debris and categorical influencing factors.

203 Figure 4a illustrates that sandy soil, which totalizes about 70% of all debris, was the
 204 most vulnerable soil, followed by clay (22%), silt loam (7%) and lithosols (1%). Similarly,
 205 sandy soil not only ranked higher in terms of frequency but also in terms of size. The high
 206 sensitivity of sandy soil to rainfall-induced debris may be due to its high coefficient of
 207 permeability which facilitates fast saturation of topsoil during the rainfall period that induces
 208 shallow debris (Lee et al. 2013). Overall, about 73.85% of all debris was shallow, that is, below
 209 500m³, 18.68 % (500-2000m³) was small, 5.71% (2000-5000m³) was medium, and only 1.76%
 210 were critical, i.e., above 5000m³, as depicted in Fig. 4b. Figure 4c, illustrates that about 74%
 211 of landslide-induced debris occurred in Gangwon and Seoul; this made the two provinces more
 212 vulnerable than other regions. South and North Gyeongsang provinces ranked third and fourth
 213 with 7% (25 cases) and 5% (18 cases) of all debris inventory, respectively.

214

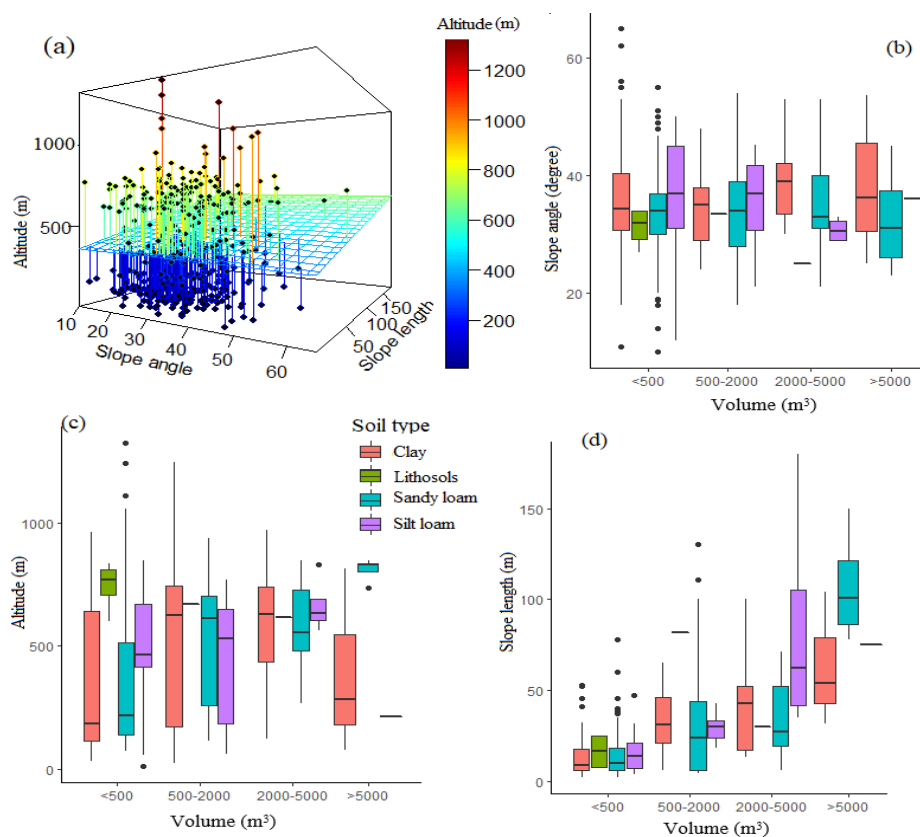

215 Figure 4. Distribution of debris: (a) debris' volume (in m³) per soil types, (b) debris'
 216 frequency per volume, and (c) debris' frequency per provinces.

217

218 To examine the relationship between continuous explanatory variables and their effect
 219 on the size of debris, 3D scatter plots and boxplots were presented (Fig. 5). It was observed on
 220 the 3D scatterplot that most debris occurred at slope between 20° and 40° (Fig. 5a), this was
 221 also confirmed by the boxplot (Fig. 5b), where few exceptions were observed for shallow
 222 debris for clay and sandy soil where debris occurred at small or at very large slope angles as
 223 outliers. Shallow debris was independent of the slope angle as depicted in Fig.5c; outliers were

224 scattered on all slope angles, and as the size of debris increased, the occurrence converged at
225 slope between 20° and 40°. There was a pseudo-decreasing trend between altitude and size of
226 debris (Fig. 5c), the highest altitudes (above 600m) were associated with shallow debris and
227 critical debris occurred at altitude between 200 and 900m. On the other hand, a quasi-increasing
228 relationship between size of debris and slope length was observed in all type of soil (Fig. 5d).
229 Debris below 500m³ was associated with slope length below 80m, the highest quartile was
230 about 140m associated with clay soil of above 5000m³ of debris size.

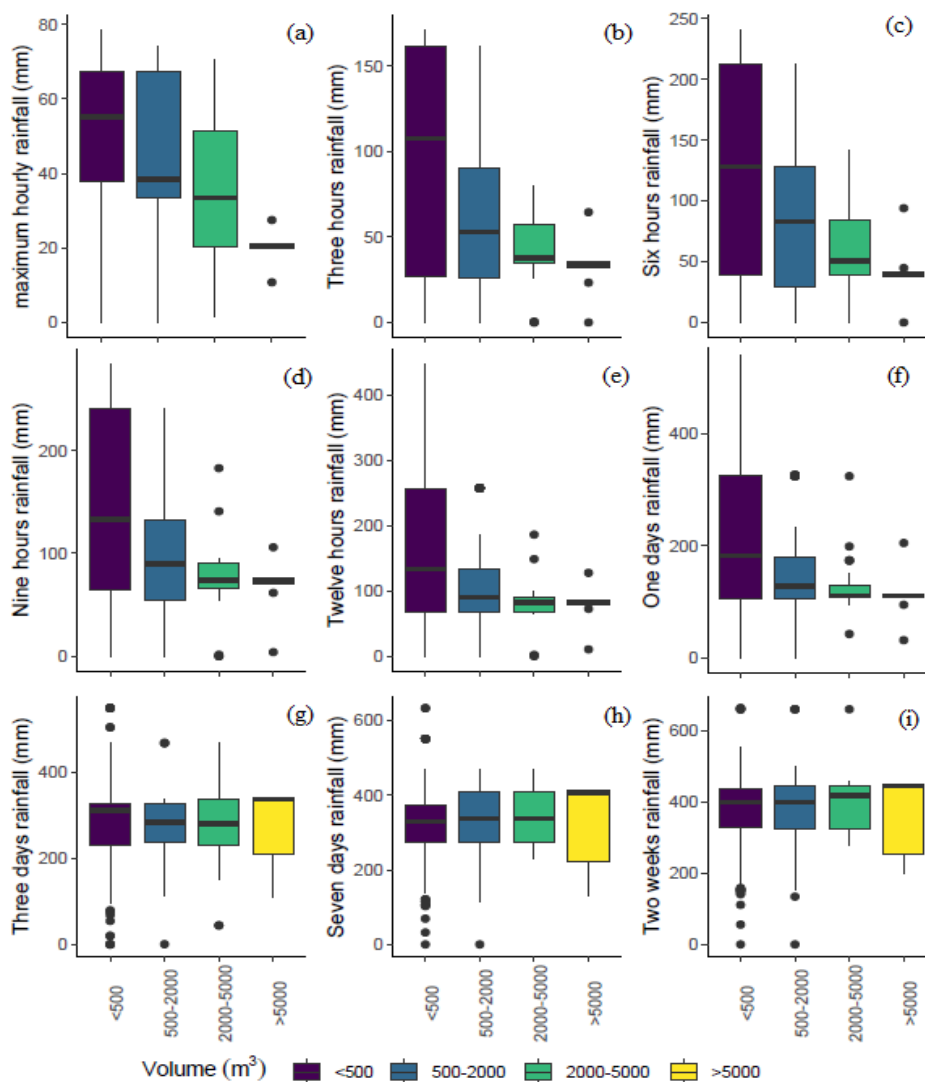

231

232 Figure 5. Distribution of debris and continuous predictors: (a) 3D Scatter plot between altitude,
233 topographic slope and slope length, (b) boxplot of volume of debris per slope angle and
234 soil types, (c) boxplot of volume of debris per altitude and soil types, and (d) boxplot of
235 volume of debris per slope length and soil types.

236 The analysis of the relationship between the size of debris and rainfall over different
237 time intervals has shown that short time rainfall was associated with shallow debris(fig.6 a-f),
238 as the cumulative time interval of rainfall increased, the debris size increased and stabilized at
239 three days cumulative rainfall(Fig. 6g). we observed that the increase in severity of debris was
240 associated with lower precipitation as reflected in the yellow boxplot for debris above
241 5000m³(Fig. 6. g-f), the precipitation of occurrence was below the corresponding median
242 rainfall. Therefore the lower precipitation on prolonged time greater or equal to three days was
243 responsible for severe debris. On the other hand, short-duration heavy rains were responsible
244 for shallow debris(Polemio and Petrucci 2000).The relationship between shallow debris and
245 heavy rain was reflected in the boxplot representing debris below 500m³(Fig. 6 a-f), where the
246 interquartile range of precipitation was large.

247

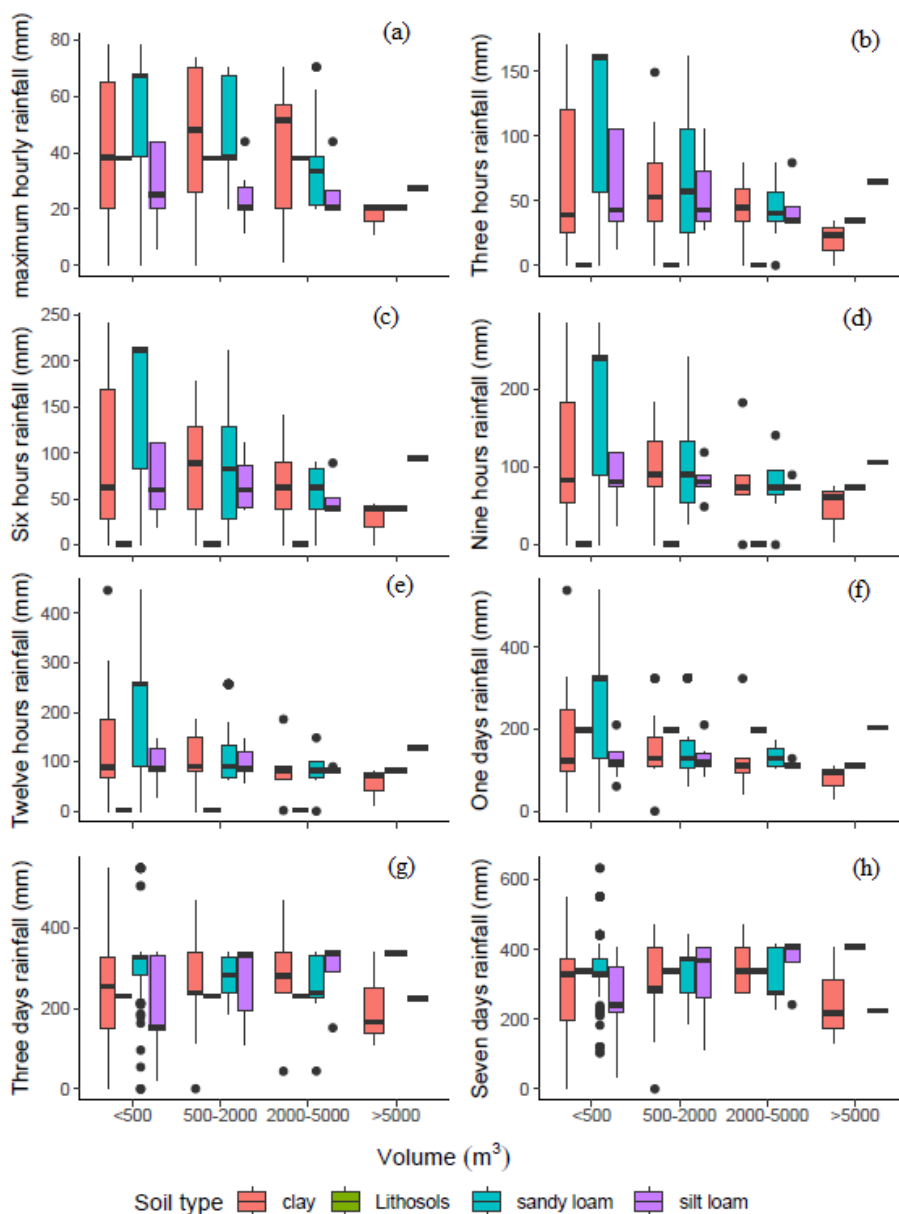

248 Figure 6. Distribution of severity of debris per antecedent rainfall grouped in different time
 249 intervals

250

251 The precipitation at the time of the incident exhibited an inverse relationship between
 252 the size of debris and rainfall intensity (Fig. 7 a-f). From three days' cumulative of antecedent
 253 rainfall, the relationship became almost constant in all time-based cumulative rainfall (Fig. 7
 254 g-h). The rainfall of lower intensity falling over a prolonged period was observed to trigger the

255 large size of rainfall-induced debris (Tang et al. 2017; Rivas et al. 2022). The threshold for the
256 triggering factor was the rainfall duration of atleast 3days (Chinkulkijniwat et al., 2020;
257 Rahardjo et al., 2020). In terms of soiltype, clay exhibited shallow debris at lowest
258 precipitation followed by sandy soil. The median of the occurrence of shallow debris was the
259 lowest for silt loam compared with other soil types. From three days cumulative rainfall(Fig.
260 7g), the median of occurrence of all size of debris stabilized around 300mm of precipitation
261 and clay was more likely to produce severe debris.

262

263 Figure 7. Relationship between rainfall and the size of debris.

264

265 **3.3. Method Description**

266 The analysis, construction, and evaluation of models were done in the following
267 chronological order as depicted in Fig. 2. First, the data set was curated: formatting the
268 variables to match their types, that is, numerical variables into a numerical format, and
269 categorical variables into factor and ordered factors according to their natural characteristics
270 (Table 1). Second, the dataset was split into training and test set. Third, the four machine
271 learning algorithms (Kainthura and Sharma 2022; Su et al.,2022), were applied to the training
272 and test set on all variables consecutively. Finally, confusion matrices for each method were
273 generated to compare the performance based on the overall accuracy and *kappa*. The variable
274 ranking plot was generated to identify the cause of differences in the predictive power of the
275 four methods.

276 All analyses were done using the following packages in R software: Caret (Max 2022)
277 for the creation of confusion matrix, dplyr (Wickham et al. 2022) for data manipulation and
278 formatting, MASS for running proportional odd logistic model, Random Forest for running the
279 random forest algorithm, Xgboost for running extreme gradient boost, SVM for supporting
280 vector machine, Ggplot2 (Wickham 2016), alluvial (Brunson 2020) for plotting, and Matrix for
281 creation of sparse matrix which is used in training extreme gradient boosting.

282 Variable importance is a systematic approach for identifying the contribution of input
283 variable in the prediction of the outcome variable in the predicative model. For graphical
284 representation of variable importance (Biecek and Burzykowski 2021), the plot was made using
285 DALEX libraries (Biecek 2018) and the e1071 package (Meyer et al. 2021) in R (Team 2021).
286 This plot ranks variables according to its influence on the predictive power of the model.

287 The selected methods for modeling were chosen based on low parsimony and are
288 frequently applied to ordered outcome problems. The predictive performance for each model
289 was evaluated using confusion matrix information accuracy and *kappa* (Caelen 2017). The

290 kappa statistic k measures the agreement between the observed and predicted values to quantify
291 the ability of the model to classify the output variable into their appropriate classes or categories.
292 Let both the observed Y variable and predicted Z variable have g categories or levels. Let f_{ij}
293 be the frequencies of observations in the i^{th} categorical output variable Y and the j^{th} category
294 of the predicted values, then the frequency table known as the confusion matrix can be arranged
295 as follows:

	Z=1	Z=2	...	Z=g
Y=1	f_{11}	f_{21}	...	f_{1g}
Y=2	f_{21}	f_{22}	...	f_{2g}
⋮	⋮	⋮	...	⋮
Y=g	f_{g1}	f_{2g}	...	f_{gg}

296

297 The observed (actual values) ratio of agreement between Y and Z is expressed as:

298
$$p_0 = \frac{1}{n} \sum_{i=1}^g f_{ii} \quad (1)$$

299

300 and the expected agreement by chance is defined as:

301
$$p_e = \frac{1}{n^2} \sum_{i=1}^g f_{i+} f_{+i} \quad (2)$$

302

303 where f_{i+} is the total for the i^{th} row f_{+i} is the total for the i^{th} column. The value of kappa is
304 the estimate of the population coefficient calculated using the following formula:

305
$$k = \frac{\text{Pr}[Y=Z] - \text{Pr}[y=z|Y \text{ and } Z \text{ are independent}]}{1 - \text{Pr}[y=z|Y \text{ and } Z \text{ are independent}]} \quad (3)$$

306

307 The confusion matrix is useful for analyses, control tunes of different classifiers, and
308 identification of a combination of classes with its recognition values or rates (Susmaga 2004).
309 The confusion matrix is a ($g \times g$) dimension table (matrix) which matches predicted values
310 from the model vs. actual values from the dataset, where g stands for levels of the outcome
311 variable, entries on the diagonal represents the correct classification, and non-diagonal
312 elements represent misclassification. The accuracy is defined as the ratio of correctly classified
313 entries and the sum of correctly classified and misclassification. The accuracy of the model is
314 compared to the value of the No information rate (NIR). The NIR is the baseline for assessing
315 performance, not 0.5. For the model to be useful (better than random guess), the lower bound
316 for a 95% confidence interval (CI) of prediction must be greater than NIR (Garson 2021). The
317 next paragraphs describe each method in detail.

318 The proportional odds logistic model (POLR) (McCullagh 1980) is one of the usefull
319 methods designed to handle ordered or ranked outcome variables when the outcome categories
320 (levels) are more than two. This model is constructed based on cumulative probability
321 distribution (Brant 1990), $y_j = \Pr(y \leq j)$ and is expressed in the form:

$$322 \quad \text{logit} [y_j / (1 - y_j)] = \theta_j - \beta^t X \quad (4)$$

323 where y is a set of N and independent observation taking values $j = 1, 2, \dots, k$, X is a
324 vector of independent variables, $\theta_1 < \theta_2 < \dots < \theta_{k-1}$ and β^t are unknown parameters. To use
325 ordinal regression, assumptions must be satisfied.

326 To use the proportional odds logistic regression, the proportional odd assumption or the
327 parallel regression conditions must be satisfied. The first states that no independent variable
328 has a disproportionate effect on any level of the dependent variable (McNulty 2021). If this
329 condition is not satisfied, other methods such as adjacent logit models may be used (Agresti,
330 2010; Harrell, 2015). To test the parallel regression, the Brant-Wald test is used and this test

331 compares the general ordinal logistic regression (with no assumption of proportional odd) with
332 POLR. It is the test of significance in the difference between the two models, which produces
333 chi-square statistics. If the p-value of each of the different coefficients of variables in the model
334 is greater than 0.05, then the parallel regression assumption holds (Brant 1990) or the
335 assumption is violated otherwise. Binary logistic regression is frequently used for landslide
336 susceptibility mapping (Yesilnacar and Topal 2005; Yilmaz 2009; Lin et al. 2017; Lombardo and
337 Mai 2018; Sun et al. 2021), the ordered logistic regression is an extension for binary logistic
338 applied to solve problems with multilevel ordered outcomes (Brant 1990).

339 The second used method was the Random Forest which is a classification and regression
340 methods. The RF algorithm (Breiman 2001) is a combination of tree predictors and every tree
341 is made based on values of random vectors, which are sampled independently using the same
342 distribution to create all trees of the forest. In this study, the RF classification method (Biau
343 and Scornet 2016; Lechner and Okasa 2020;) is appropriate due to its capability to handle
344 multiple outcome-related problems (Diaz-Urriarte and de Andrés 2005). It was applied in
345 different regions for landslide susceptibility mapping (He et al. 2021; Sun et al. 2021; Huang et
346 al. 2022).

347 The third used method is SVM, which was widely used for mapping the likelihood of
348 landslides (Lee et al., 2017). Among the multiple class prediction methods, the SVM method
349 performed better for protein fold recognition (Ding and Dubchak 2001; Huang and Zhao 2018),
350 landslide hazard (Hong et al. 2015), landslide spatial prediction (Pham et al. 2018), etc. SVM
351 performed not only in multiclass problems but also better in ordered multilevel problems and
352 it worked better than traditional regression methods (Li et al. 2012). More details about the
353 SVM algorithm is described by Noble (2006).

354 The last but not least to choose was the EGB. Extreme gradient boosting is also a machine
355 learning algorithm known for its high-speed performance and efficient prediction accuracy

356 (Chang et al. 2018). The algorithm is based on Friedman's work (Friedman 2001) and
357 implemented in R under the package xgboost (Chen et al. 2015). This method is known for its
358 high performance on larger sample sizes (Georganos et al. 2018).

359 **4. Analysis & discussion**

360 To identify the suitable model for the prediction of the size of debris, previously discussed
361 methods were explored, and results were summarized and compared in this section.

362 **4.1 Debris prediction using POLR**

363 The significance of the observed relationship between the size of the debris and the
364 associated explanatory variables was measured using proportional odd logistic regression.
365 Variable selection was made using backward selection (Andersen 2010). The above coefficients
366 can be interpreted as follows: taking into consideration of p-values, and for each case supposing
367 that all other coefficients were held constant, the decrease in three hours' rainfall is associated
368 with a 94% lower odd the size of debris, an increase in six hours' rainfall was associated with
369 4% increase in higher odd of the size of the debris (Table 2).

370 Table 2. POLR model coefficients.

Variables	Coefficient	P value	Odds ratio
Three hours rain	-0.051	<0.01	0.949
Six hours rain	0.039	<0.01	1.040
One day rain	-0.009	0.01	0.990
Slope length	0.039	<0.01	1.040
altitude	0.001	0.02	1.001
Drainage: Good	1.246	0.13	3.477
Drainage: Very good	1.818	0.04	6.164
Intercepts:			
<500 500-2000	2.313	<0.01	10.105
500-2000 2000-5000	4.455	<0.01	86.102
2000-5000 >5000	6.428	<0.01	619.397

371

372

373 The goodness of fit and model diagnostic result shows that McFadden pseudo- R^2 was
374 0.23 where the values between 0.2 and 0.4 indicated an excellent fit (Louviere et al. 2000). To
375 test proportional odd assumptions, the Brant-Wald test (Brant, 1990) was used, and the result
376 was summarized in Table 3. It shows that all probabilities for all variables including the
377 omnibus are greater than the 0.05 threshold, except for slope length, which proves that the
378 parallel regression assumption is satisfied.

379 Table 3. Parallel regression assumption test.

Test for	X ²	df	Probability
Omnibus	12.6	14	0.56
Three hours rain	1.76	2	0.41
Six hours rain	1.18	2	0.56
One day rain	1.18	2	0.55
Slope length	7.1	2	0.03
altitude	1.31	2	0.52
Drainage	0.19	4	1

380

381 The effect plot was used to demonstrate the change, in the likelihood of occurrence of
382 landslides of a given volume, associated with the change in selected predictors. Figure 7 depicts
383 the variation of probability of landslides of a given volume per three days' rainfall and slope
384 length. The likelihood of occurrence of debris below 500m³ was directly proportional to an
385 increase in the rainfall for the slope length below 30m. There was a decrease in the occurrence
386 of debris larger than 500m³ as the rainfall increased. This decrease is an indication that shorter
387 slope length was associated with a shallow debris (First column of Fig. 7). Moving from the
388 first to the 4th column, the probability of shallow debris (below 500m³), the probability shifted
389 from 0.9 to 0.6 as slope length increased from 30m to 170m, and the long tail of probability
390 plots for debris of size above 500m³ disappeared as the slope-length and rainfall increased. This
391 shifted up the probability curve for critical debris from 0.2 to 0.9 for slope length below 30m
392 to 0.9 for slope length above 110m, respectively.

393
 394 Figure 8. Effect of three hours of rainfall and slope length on size of debris.

395

396 Figure 9 illustrates that the maximum size of debris occurred at slope lengths above 50m
 397 and with rainfall between 80mm to 110mm. Looking at the two upper light hand corners of Fig.
 398 9, the probability of occurrence of debris above 5000m³ peaked at slope length above 100m
 399 and fade as the rain value increased, this fading associated with rain does not mean that there
 400 is an inverse relationship with rainfall but it associated with the rarity of heavy rain in the
 401 dataset. The probability of occurrence of shallow debris decreased as both altitude and slope
 402 length increased. On the other hand, the chance of occurrence of debris of size between 500m³
 403 and 2000m³ increased with slope length and attained the maximum length between 70 and 80m
 404 with the maximum probability of occurrence of 0.6, and the last one decreased for slope length

405 above 100m. For the medeium sized debris, the maximum probability of occurrence was 0.7
406 and associated with slope lengths between 120m and 150m. The probability of occurrence of
407 critical debris increased exponentially with slope length and altitude.

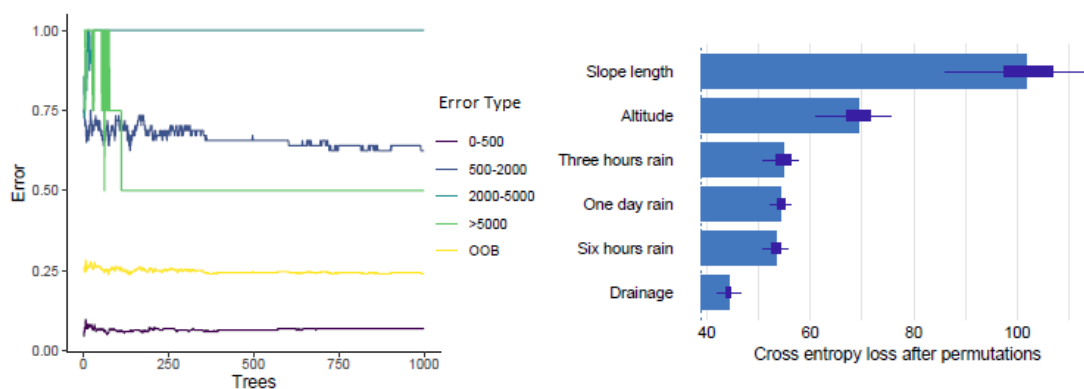

408
409 Figure 9. Effect of altitude and slope length on size of debris.

410 The intuitive explanation of the continuous decrease with shallow debris is associated
411 with the cumulative character of the model, which means that, what looks like a decrease is not
412 a real decrease, it is a shift from a lower level to a higher level associated with an increase in
413 variables into consideration. For altitude below 300m, shifting from a size below 500m³ to 500-
414 2000m³ happened at 20m of slope length, while shifting from 500-2000m³ to 2000-5000m³ and
415 above occurred at slope length between 60 to 80m.

416 **4.2 Debris prediction using RF**

417 The random forest model was run on the training set of 304 observations. The number of
418 grown trees was 1000, the variable tried at each split was 4, and the out-of-bag error estimates
419 (OOB) error rate was 24.42%. Figure 10a depicts the predictions of a class below 500m³ that
420 had the least errors. Since the model is for classification, to calculate the prediction error, the
421 model was run on the test set. The variable importance graph illustrates the slope length was
422 the most contributing variable to the model accuracy (Fig. 10b). The mean decrease Gini (cross-
423 entropy loss after permutation) value is the measure of the contribution of each variable to the
424 homogeneity of nodes and leaves in the random forest (Martinez-Taboada and Redondo 2020).
425 The higher the value, the more important the variable is, which exhibited that slope length is
426 more influencing factor for the size of debris.

427

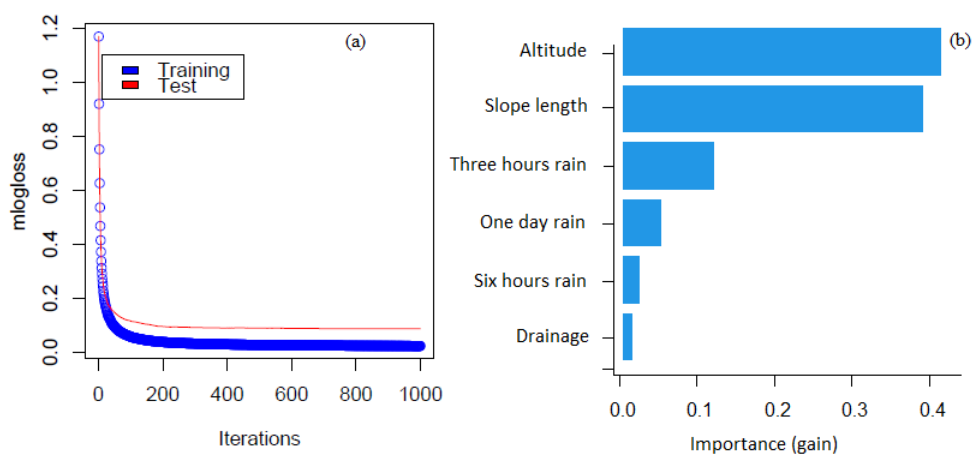

428 Figure 10. RF model: (a) training error rate, and (b) variable importance.

429 **4.3 Debris prediction using EGB**

430 To run the EGB, the train and test set were transformed into a sparse matrix, as it is run
431 on numerical data matrices (Chen et al. 2022). The optimum model was obtained at the 881
432 number of iterations and the learning rate of 0.3. Since the task was a multi-classification, the
433 multi: softmax objective was used (Chen et al. 2022). The evaluation metric was mlogloss

434 (Multi-class log loss) (Kabani and El-Sakka 2016). While training the model, the minimum
435 mlogloss were 0.025 and 0.088 for the training and test sets respectively (Fig. 11a). The
436 difference between training and the test error is due to the larger variance associated with the
437 fewer number of observations in the test set. The extreme gradient boosting associated with
438 higher importance to slope length, altitude, slope and three hours of rainfall, respectively (Fig.
439 11b).

440

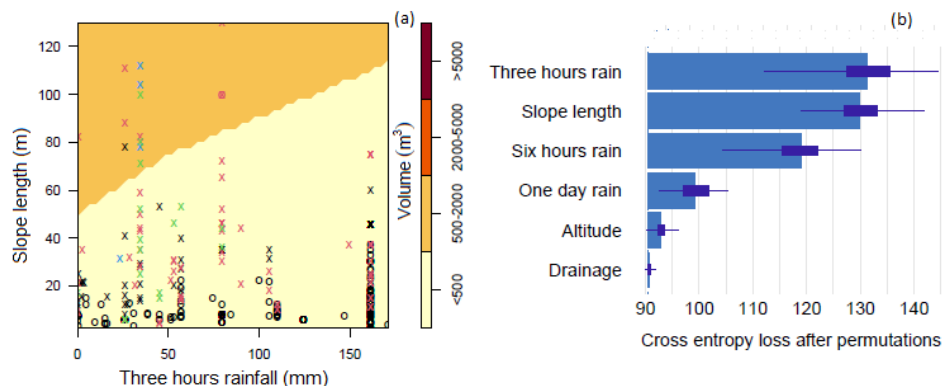

441 Figure 11. EGB model: (a) error rate and (b) variable importance.

442 4.4 Debris prediction using SVM

443 The support vector classification model with linear kernel was applied, and the number
444 of support vectors was 142. The outcome of SVM model shown a higher performance rate on
445 the test than the training set. Figure 11a depicts a two-dimensional projection of train data using
446 slope length and three hours of rainfall showing different shading and support vectors. One of
447 the weaknesses of the SVM, it classified predictions into two lower classes as indicated in Fig.
448 12a, it couldn't distinguish the moderates from extreme debris. The SVM assigned higher
449 importance to slope length and three hours of rainfall as the second high ranking variable as

450 shown in Fig. 11b.

451

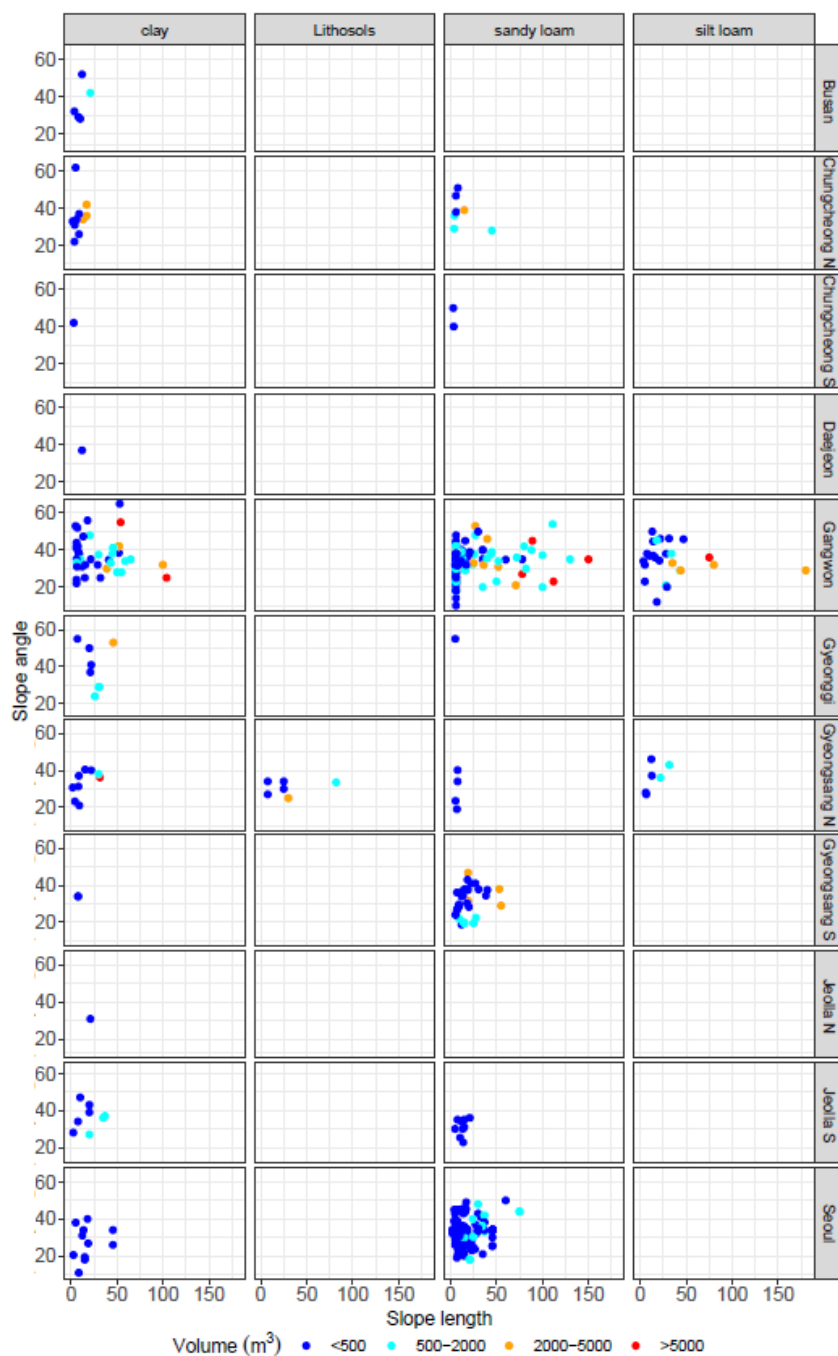

452 Figure 12. SVM model: (a) SVM classification plot, and (b) variable importance.

453 **4.4 Discussion and model suitability assessment for landslide-induced debris severity** 454 **prediction**

455 This study analyzed the relationship between the severity of landslide-induced debris. The
456 exploratory data analysis revealed that 93% of occurred debris was below 2000m³. The
457 Gangwon province and Seoul were more vulnerable regions in terms of the frequency of
458 incidents. Despite a higher frequency of debris in Seoul, their size was small compared to
459 Gangwon province with higher number of cases and more large sized-debris. To analyse the
460 significance of the relationship between the size of debris with different models ranked the
461 slope length as the most influential variable for the size of the debris. To visualize the
462 association of the slope length with the size of debris, the scatter plot (Fig.13) revealed that the
463 pattern of increasing trend of slope length and size of debris was more remarkable across all
464 provinces, shallow debris were associated with slope length below 50m. The debris cases were
465 clustered between 20° and 40°, as depicted in Fig.13, and critical debris tended to be clustered
466 around 30 degrees; the association of slope angle and size of debris was not statistically
467 significant. For the soil-debris size relationship, sandy soil and clay were associated with a

468 higher frequency of debris; they exhibited shallow debris in all provinces except in Gangwon
469 where severe debris occurred. It was observed that even though the silt loam soil was not highly
470 frequent, it was vulnerable to severe debris as the slope length increased. Gangwon province
471 was the region where the increasing relationship between the size of debris was observed, other
472 provinces were not prone to severe debris.

473

474 Figure 13. Province-wise scatter plot of debris' size per slope length, slope angle and soil

475 types.

476

477 To assess the suitability of utilized models, it was observed that the ordinal regression
478 prediction power was low due to its inherent weakness; it does not perform well on the
479 imbalanced dataset (Agresti 2010). That is, the outcome variable has some more prevalent
480 levels than others. It also estimates the coefficient using maximum likelihood techniques,
481 which require a large sample size, the used dataset was highly imbal-
482 anced. Figure 7 revealed that almost 80% of all occurred debris was shallow, as result, the
483 model coefficients became unstable with larger prediction intervals. Despite the weakness, the
484 ordinal model has the effect display (Fox and Weisberg 2019), which clearly shows the effect
485 of each variable to each extent and the associated probability. The predictive performance for
486 each of the four discussed methods was summarized in Table 4 to facilitate their comparison.
487 The random forest model performed well in all cases on the training set and validation as well.
488 This model associated the influencing factor with higher importance and lower importance to
489 rain-associated variables. RF prediction accuracy was very high on the training set (0.93), and
490 0.90 on the test set. The prediction at 95% of confidence interval width ranged from 0.84 to
491 0.94 on training and test sets, respectively. The NIR shifted from 72.28% to 74.17%, and this
492 small increase is due to a small sample of the validation set.

493 The model accuracy for POLR was quite moderate based on the *kappa* value of 0.38. The
494 performance accuracy was better, the no information rate, $NIR=0.7228 < 0.7314$ lower
495 boundaries of CI on the training set. This last condition was not satisfied for the test set, that is
496 $NIR=0.74$ was higher than 0.69, which was the lower CI for the prediction interval on the test
497 set. Based on the p-value for the prediction on test $0.26 > 0.05$, the performance was not reliable.
498 This is confirmed by the overall performance metric *kappa* =0.30, which was quite moderate.

499

500

501 The EGB model ranked the second best model after the RF, it satisfied all prediction
502 conditions the overall performance ($kappa = 0.6121$) was slightly below the random forest
503 0.7273 . The SVM model result was satisfactory for the training set. The lower bound of very
504 close to the information rate and the overall performance was moderate ($kappa=0.32$), the
505 weakness of the model was its incapacity to distinguish the moderate debris from the extreme
506 ones; as result, it predicted all debris into two lower categories in Fig. 8a. The NIR fell into the
507 prediction interval on the validation set, and the p-value was $0.11 > 0.05$, which is an indication
508 of moderate prediction accuracy.

509 Table 4. Model accuracy statistics for the four methods.

Model accuracy statistics						
Method	Data	Accuracy	95% CI	NIR	P-Value	kappa
RF	Train	0.93	(0.89, 0.95)	0.72	<0.001	0.82
	Test	0.90	(0.84, 0.94)	0.74	<0.001	0.72
POLR	Train	0.78	(0.73, 0.82)	0.72	0.011	0.38
	Test	0.76	(0.69, 0.83)	0.74	0.26	0.3
SVM	Train	0.77	(0.72, 0.82)	0.72	0.015	0.32
	Test	0.78	(0.71, 0.85)	0.74	0.11	0.3
EGB	Train	0.86	(0.81, 0.89)	0.72	<0.001	0.63
	Test	0.86	(0.79, 0.91)	0.74	0	0.6

510

511 The landslide-induced debris prediction is an extension of landslide susceptibility mapping and
512 may be useful in the quantification and prediction of debris resulting from a rainfall-induced
513 landslide. This quantification can facilitate risk management (Ho and Ko 2009), in the
514 identification of regions prone to severe debris and the making of policies for mitigation
515 (Carmela and Mario Parise 2022). For example the decision of planting more vegetation that
516 fits the conditions of the region to strengthen the soil or deciding an appropriate activity to be
517 done in a given region to improve stability ,safety and efficient land use (Mayer et al. 2008) .
518 Furthermore, some activities in regions prone to severe debris may be prohibited for the safety

519 and well-being of the public(Frattini et al. 2010; DeGraff and Romesburg 2020; Di Napoli et
520 al. 2020). In addition, the model may serve the disaster manager to create appropriate funds
521 for post-disaster recovery. For example, if a region is expected to have shallow debris, the
522 manager may establish a small fund for paying minor labour to repair the damaged environment.
523 In extreme cases, a big fund may be created to pay for machinery and construction of preventive
524 walls, plantation, and cost of machinery to remove debris in the affected region, to rehabilitate
525 the impacted economic activities in the neighbourhood (Kachi et al. 2016). Due to the lack of
526 financial data associated with the inventories the cost of post-disaster recovery was not
527 estimated, more studies in the future may be carried out to fill this gap. The approach in this
528 paper is valid for the studied area based on the user input data; more research in the future may
529 be conducted to know whether the findings in this paper are general for regions with different
530 characteristics or settings.

531 **6. Conclusions**

532 The study analyzed the relationship between the size of rainfall-induced debris and causal
533 factors, i.e., time-based cumulative rainfall and influencing factors: soil types, vegetation, and
534 geomorphology features. The exploratory data analysis revealed that the Gangwon province is
535 prone to more frequent and more severe landslide-induced debris. Soil-related information
536 revealed that the landslide-induced debris was more frequent in sandy soil and more severe,
537 but its influence was not statistically significant in the predictive model. The region with non-
538 perfected drainage systems also experienced severe debris. The regions with old timber that
539 experienced fire had a higher debris likelihood. To examine the significance and to identify the
540 suitable model for landslide-induced debris severity, four predictive modeling techniques i.e.,
541 POLR, RF, EGB and SVM, were applied to examine the causal and influencing factors of the
542 severity of rainfall-induced debris in South Korea. The performance metrics, accuracy and

543 *kappa* were applied to compare the predictive power of each of the four methods. The findings
544 of this research revealed that three hours' rainfall, one-day rainfall, and slope length were the
545 most influencing factor and altitude took the second place. This finding was consistent with the
546 results of Lee et al. (2012), stating that short-duration rainfalls were responsible for landslides
547 and are the cause of their severity. The comparative analysis has shown that random forest had
548 better predictive power with an accuracy of 90% and *kappa* = 0.72, and extreme gradient
549 boosting followed with an accuracy of 86% (*kappa* = 0.6). The last two methods SVM with an
550 accuracy of 78% (4% above NIR), and POLR performance was moderate at 76%, which is
551 only 2% above 74% performance decision basis (No information rate NIR), but we did not
552 have enough information to confirm their use as a basis for creation early warning system for
553 rainfall-induced extreme debris. This is because POLR does not perform well on limited and
554 imbalanced data (Rahman et al. 2021), which is the root cause of a wide range of prediction
555 intervals. Thus, RF and EGB may be used as a suitable models for rainfall-induced debris
556 prediction. The creation of a nationwide landslide database would solve the shortage of reliable
557 data and allow the usage of more alternative methods, which will result in more improved
558 models. The findings of this research may be used for the elaboration of rainfall-induced debris
559 mitigation policies such as post-disaster rehabilitation planning and land use management.
