Abstract: In mountainous areas, damage caused by debris flows is often aggravated by subsequent dam-burst floods within the main river confluence zone. On 30 August 2020, a catastrophic disaster chain occurred at the confluence of the Heixiluo Gully and Niri River in Ganluo County, Southwest China, consisting of a debris flow, the formation of a barrier lake and subsequent dam break that flooded the community. This study presents a comprehensive analysis of the characteristics of the two hazards and the resulting damage to buildings from the cascading hazards. The peak discharge of the debris flow in the gully mouth reached 1,871 m³/s. Following the dam break, the flood with a peak discharge of 2,737 m³/s, significantly altered the main river channel, causing a fourfold increase in flood inundation compared to an ordinary flood. Three hazard zones were established based on the building damage patterns: (I) primary debris flow burial; (II) secondary dam-burst flood inundation and (III) sequential debris flow burial and dam-burst inundation. Vulnerability curves were developed for Zone (II) and Zone (III) using impact pressures and inundation depths, and a vulnerability assessment chart is presented that contains the three damage categories. This research addresses a gap in the vulnerability assessments of debris flow hazard cascades and can support future disaster mitigation within confluence areas.

Keywords: Multi-hazard risk, Debris flow, Dam-burst flood, Building damage, Vulnerability analysis.

1 Introduction

In mountainous areas, debris flows frequently block rivers and form temporary dammed lakes. The subsequent breach of these dammed lakes can result in a high-magnitude outburst flood (Yan et al., 2020). The hazard cascade consisting of debris flows and subsequent dam-burst floods usually devastate residential buildings in confluence zones. For instance, a large-scale debris flow occurred in the Wenjia Gully in Sichuan Province, Southwest China, on 13 August 2010 and completely blocked the Mianyuan River, which formed a dammed lake 1,650 m long, 420 m wide,

35 and 12 m deep. Then, the dammed lake breached and caused 7 fatalities and extensive damage to
36 479 houses (Yu et al., 2013).

37 Multi-hazard analyses that incorporate potential hazard interactions have gained significant
38 attention in recent years (Liu et al., 2015; Gallina et al., 2016; Tilloy et al., 2019; Luo et al., 2023).
39 However, vulnerability assessments in risk analysis rarely consider the effects of hazard
40 interactions (Luo et al., 2023). Argyroudis et al. (2019) introduced a new methodology for
41 evaluating the vulnerability of transport infrastructure to multiple hazards. This approach is
42 comprised of six steps and includes numerical and fragility models. Progress has been made in
43 assessing the risk of buildings exposed to multiple hazards by considering the interaction between
44 an earthquake and other hazards, such as dam breaks, flash floods, and tsunamis. Korswagen et al.
45 (2019) proposed a methodology for assessing structural damage resulting from coupled hazards
46 and used it to assess the vulnerability of a masonry building subjected to an earthquake and an
47 earthquake-triggered dam break. Furthermore, Park et al. (2012) developed collapse fragility curves
48 for earthquake and tsunami effects using a numerical model. Gautama and Dong (2018) outlined
49 the vulnerability of vernacular stone masonry buildings to the flash floods that occurred after the
50 Gorkha earthquake. Residential buildings in Nepal were found to have up to 300% damage
51 resulting from the combined earthquake and subsequent flash flood. Petrone et al. (2020) simulated
52 the response of reinforced concrete frames to earthquake and tsunami inundation, yielding fragility
53 curves that showed a median decrease of less than 15% in terms of tsunami resistance when exposed
54 to cascading hazards as compared to tsunami-only fragility functions.

55 The evaluation and mitigation of the multiple risks posed by debris flows and dam-burst floods
56 in a confluence zone require a multi-risk analysis that considers hazard interactions and their
57 cumulative effects on building vulnerability. Most studies on debris flow and dam-burst floods
58 mainly focus on numerical simulations and the evolving processes of hazard cascades (Cutter, 2018;
59 Ning et al., 2022; Chen et al., 2022), but studies on the vulnerability of building to hazard cascades
60 are scarce. The vulnerability of buildings to the cumulative impact of debris flow and flash flood
61 may differ from the sum or sequence of vulnerability resulting from a single debris flow or flash
62 flood (Kappes et al., 2012). The effect that simultaneous hazards have on building vulnerability
63 remains inadequately addressed, with only a few studies available (Kappes et al., 2012). Luo et al.
64 (2020) proposed a framework for developing physics-based vulnerability models for buildings
65 exposed to multiple surges of debris flows. Cumulative damage effects resulting from sequentially
66 occurring debris flows were quantified by assessing the physical damage from primary debris flows.
67 However, this approach may not apply directly to the debris flow-dam-burst flood hazard cascade.

68 Field investigations have shown that the pattern of damage to buildings in the confluence area
69 of debris flow and flood is not consistent with those from the debris fan or on the floodplain. Our
70 field investigations have revealed that the pattern of damage to buildings in the confluence area of
71 debris flow and flood is distinct from those observed in areas affected by debris flow alone or by
72 flood alone. Debris flow usually causes devastating damage to settlements on the fan, and the
73 subsequent dam-burst flood significantly increases the damage (Xu et al., 2014; Yu et al., 2013).
74 The risk amplification and cumulative effect on building vulnerability resulting from successive
75 debris flows and dam-burst floods are not entirely clear. Therefore, in-depth analysis is essential
76 for assessing the risks posed by the debris flow hazard cascade to develop a successful emergency
77 management plan.

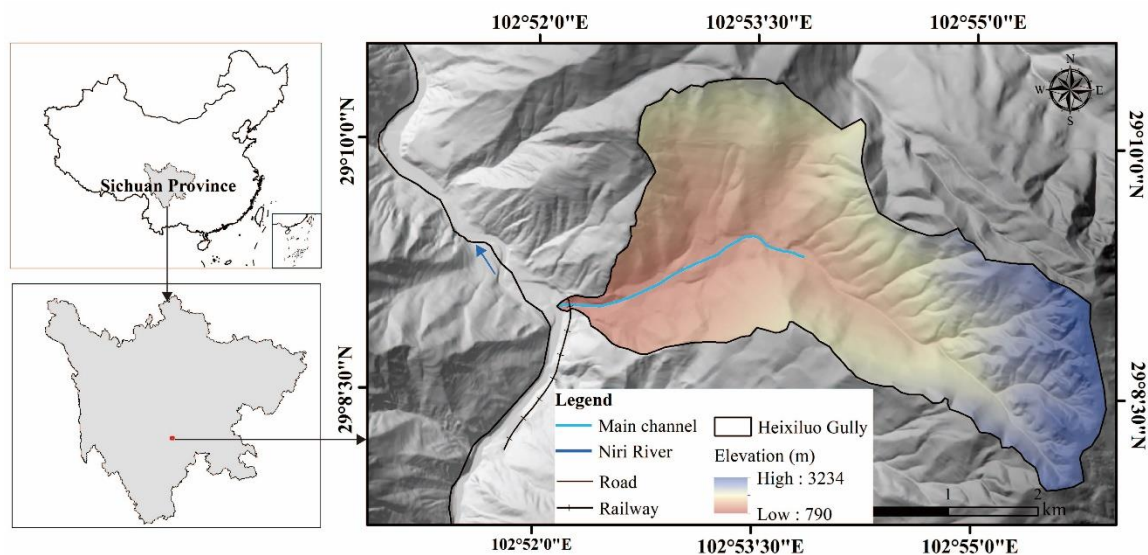

78 On August 30, 2020, a catastrophic debris flow and dam-burst flood occurred in the Niri River,
79 Ganluo County, Sichuan Province, Southwest China. The debris flow-flash flood event killed 3
80 people and caused serious damages to local infrastructure, including the destruction of 110
81 buildings, the Chengdu-Kunming railway bridge near the gully mouth, 1.2 km national road, and 5
82 highway bridges along the main river. This study aims to comprehensively analyze the damage to
83 buildings caused by the Heixiluo debris flow-dam-burst flood disaster chain. Firstly, we calculated
84 the dynamic characteristics of the debris flow and outbreak flood damage. We then systematically
85 investigated and summarized the building damage characteristics, and compared the vulnerability
86 of buildings considering different damage patterns. Finally, we discuss how the damage was
87 amplified by the chain and offer suggestions for hazard mitigation.

88 **2 Study area**

89 The study area is located in Ganluo County, Sichuan Province, Southwest China, which
90 includes the Heixiluo Gully and the confluence area along the Niri River. Ganluo County lies north
91 of the Liangshan Yi Autonomous Prefecture, occupying the alpine canyon zone in the transitional
92 region between the western margin of the Sichuan Basin and the Qinghai-Tibet Plateau (Fig. 1).
93 The geographic boundaries of the study area span from 102°27' to 103°01' east longitude and from
94 28°38' to 29°18' north latitude. Ganluo County covers a total area of 2150.97 km² and had a
95 permanent population of 205,991 at the end of 2020.

96 Ganluo County consists of an erosional tectonic landform that is defined by two primary
97 structures, namely Sichuan-Yunnan north-south structure and the Qinghai-Tibet Yunnan zeta-type
98 structure. The mountain and river systems flow from south to north due to the folds, uplift, and
99 fractures of the Hengduan Mountains and the strong disruptive effect that widely distributed rivers,
100 undulating hills, ravines, and cliffs have on the study area. The valleys, which are characterized by
101 a V-shaped cross-section, have considerable depths that typically exceed 1000 meters.

102 The study area has many typical geological structures, such as the N–S trending Teke fault,
 103 Suxiong anticline, and Maanshan anticline. These faults were active during the early and middle
 104 Pleistocene and there is no discernible evidence that they were active during the late Quaternary
 105 period. The exposed strata in the study area are primarily composed of Quaternary strata (Q),
 106 Presinian Ebian Group (Pteb), and Lower Sinian Suxiong Group (Zas). The upstream area is mainly
 107 occupied by sandstone, whereas rhyolite and tuff dominate the main part of the catchment, with
 108 slate occupying the left downstream area. The study area is situated in a seismically active region.
 109 The peak ground acceleration in the study area is 0.15 g, and the peak period of the seismic response
 110 spectrum is 0.45 s. Between 1327 and 1975, 147 of $M_s \geq 2.5$ earthquakes happened, including 15
 111 $M_s \geq 5.0$ earthquakes with the highest magnitude of 7.5.

112
 113 **Figure 1** Location of the study area including the Heixiluo Gully and Niri River.

114 The Niri River is a first-order tributary in the middle reach of the Dadu River and flows from
 115 south to north and over an elevation range of 1,800–2,200 a.s.l. for most of the areas. The highest
 116 elevation in the river basin is 4,700 m a.s.l., and the lowest elevation is 1,170 m a.s.l. The study
 117 area has a subtropical monsoon climate. The average annual temperature is 16.2° and the average
 118 annual rainfall is 949 mm. The precipitation is distributed unevenly in a year. The rainfall is
 119 concentrated from April to October, with an average rainfall of 901.9 mm, accounting for 93.14%
 120 of the average annual rainfall. The precipitation varies significantly with elevation, the maximum
 121 hourly rainfall and ten-minute rainfall recorded are 40.3 mm and 14.8 mm, respectively.

122 The Heixiluo Gully is located on the right bank of the Niri River in Suxiong town, Ganluo County
 123 (Fig. 1). The coordinates of the gully mouth are $29^\circ 09' 47''$ N and $102^\circ 52' 53''$ E and the
 124 gully extends from the east to the west. The gully covers an area of 13.36 km^2 and is situated at a

125 moderate elevation on the mountainous landform. The catchment elevation ranges from 3,220 m
126 a.s.l. to 760 m a.s.l., with a relative height of 2,460 m. The main channel of the gully stretches for
127 6.93 km, with an average gradient of 0.355.

128 The field investigation indicates that debris flow initiated in the area above an elevation of
129 1,990 m a.s.l. The gradient of the channel in this area is steep, with an average value of 0.6. The
130 transportation zone is mainly located between 820 m a.s.l. and 1,990 m a.s.l. in elevation and
131 occupies an area of 5.96 km². The length of the main gully is 4.65 km, and the average gradient of
132 the main gully is 0.252. Two platforms were distributed at altitudes of 1,160 m a.s.l. and 1,030 m
133 a.s.l. and divided the main channel of the transportation zone into three parts. A narrow channel
134 developed between the platform and the deposition fan at 1,023 m a.s.l. The length and gradient of
135 the channel are approximately 670 m and 0.243, respectively.

136 **3 Data and methods**

137 We conducted field investigations on the debris flow-flash floods that occurred on 31 August
138 and 3 December 2020. The field survey mainly focused on the main transportation and deposition
139 zones. Interviews, measurements, and aerial photography were conducted to investigate the
140 formation and disaster mechanisms. The geomorphic settings of the Heixiluo Gully and adjacent
141 Niri River were carefully measured and analyzed, including the channel width, deposition and
142 erosion height, channel slope, and particle size distributions. The damage to buildings was also
143 investigated by comparing the drone photos taken before and after the disaster.

144 **3.1 Data collection**

145 The Digital Elevation Models (DEMs) collected before and after the event were used for hazard
146 cascade analysis. The pre-event DEM was converted from a 1:10000 topographic contour map
147 provided by the Sichuan Bureau of Surveying, Mapping, and Geoinformation which had a spatial
148 resolution of 10 m. The post-event DEM of the study area was produced by synthesizing high-
149 resolution aerial images captured by a Dajiang unmanned aerial vehicle (UAV) on 3 December
150 2020. To calibrate the post-event terrain, 10 image control points that were not affected by the
151 disaster were selected, and their elevation values were sampled from the pre-DEM and assigned as
152 input conditions. The mean RMS error of georeferencing of the post-event DEM was within the
153 usable range with a value of 0.1 m.

154 **3.2 Methodology**

155 The dynamic parameters of the debris flow and discharge of the dam-burst flood were calculated
156 by the formulas presented in Table 1.

Table 1 Models used in parameter calculation for this study

Category of Calculation	Applied formula	Description parameters
Debris flow density (Hu et al., 2019)	$\gamma_c = -1320x^7 - 513x^6 + 891x^5 - 55x^4 + 34.6x^3 - 67x^2 + 12.5x + 1.55$	x is the clay content in the debris flow sample. The average clay content in particles less than 0.005 mm in size accounts for 2.55%.
Debris flow peak discharge and velocity (Kang, 1987; Yang, 1985)	$Q = \frac{1}{n_c} AR^{\frac{2}{3}} J^{\frac{1}{2}}$ $n_c = \frac{1}{18.5H^{-0.42}}$ $U = \frac{Q}{A}$	A is the cross-sectional area, R is the hydraulic radius, J is the channel bed gradient, and n_c is the roughness coefficient for viscous debris flow. The method for calculating n_c was deduced from analysis of viscous debris flows in Huoshao gully in China.
Dam-burst flood discharge	$Q = \frac{1}{n} AR_n^{\frac{2}{3}} J^{\frac{1}{2}}$	A is the cross-sectional area, R_n is the hydraulic radius, J is the channel bed gradient, and n is the Manning roughness coefficient. The values of A, R_n , and J were directly measured by the field investigation.

158 The debris flow depth and velocity were obtained by numerical simulations performed using
 159 FLO-2D software (O'Brien, 1986). FLO-2D is a simple volume conservation model that can
 160 simulate non-Newtonian flows and has been employed successfully to simulate debris flows by
 161 many researchers. The input parameters in FLO-2D include Manning's n coefficient, laminar flow
 162 resistance parameter k , and empirical coefficients α and β . The estimated peak discharge at the
 163 gully mouth using Kang's equation (1987) was applied in the simulation. The data used in the debris
 164 flow simulation are presented in Table 2.

165

Table 2 Data used in the flood simulation

Discharge	Manning's n-value	Viscosity coefficient		Yield stress coefficient		Laminar flow resistance coefficient k
		α_1	β_1	α_2	β_2	
Estimated by Kang's equation (1987) at the gully mouth	0.4 (river channel), 0.2 (building in the floodplain), 0.03 (cultivated land)	3.22	5.8293	0.0612	15.877	2,285

166 Dam-burst flood hydraulics were simulated by HEC-RAS 5.0.7 (Hydrologic Engineering Center,
 167 2016) using the post-event DEM. The computation procedure employed a one-dimensional steady
 168 flow simulation and assumed a subcritical flow regime. The boundary conditions are established at
 169 all the ends of the river nodes by entering the normal depth value. The initial conditions were set
 170 using the corresponding discharge of the dam-burst flood estimated at a typical river section using
 171 Manning's equation. Manning's n coefficient, expansion, and contraction coefficients account for
 172 flow energy losses in HEC-RAS. Due to the difficulty of acquiring terrain data for the initial stage
 173 of the dam break, it was assumed that the peak discharge of the dam-burst flood formed the post-
 174 event terrain, which was adopted to simulate the dam-burst flood. T

175 To analyze the impact of debris flows on river dynamics, we also simulated an ordinary flood
 176 unaffected by debris flows using the pre-event DEM. The flood discharge was obtained from
 177 upstream hydrological observation stations located approximately 15 km from Heixiluo Gully.
 178 The Manning's n values for the river channel and floodplain were 0.4 and 0.2, respectively. These
 179 values are the suggested values for main channels that are clean and winding, have some pools and
 180 shoals, some weeds and stones, and have flood plains for cultivated areas but are free of crops
 181 (Hydrologic Engineering Center, 2016). The data applied to the flood calculations are presented in
 182 Table 3.

183 **Table 3** Data used in the flood simulation

Flood processing	Data	Data source	Manning's n -value	Expansion and contraction coefficients
Debris flow dam-burst flood	Topography	Post-event DEM of the river channel	0.5 (river channel and floodplain)	0.1 (expansion coefficient) 0.3 (contraction coefficient)
	Discharge	Estimated by Manning's equation in a typical section		
Flood not affected by debris flow	Topography	Pre-event DEM of the river channel	0.4 (river channel), 0.2 (floodplain)	
	Discharge	Record in the Yanrun Hydrometric station (located upstream 23 km from Heixiluo Gully)		

184 A vulnerability curve was developed to describe the relationship between the hazard intensity
 185 and the degree of damage to the buildings. Following the classification of the damage degrees
 186 proposed by Hu et al. (2012), the degree of damage to buildings caused by multi-hazards was
 187 determined through a comprehensive analysis of photographs taken on site and aerial images
 188 collected over the disaster scene. Hazard intensity parameters were applied, such as flow depth and
 189 average total impact pressure, with average total impact pressure calculated as $P = \rho v^2 + 0.5\rho gh$ (Zanchetta et al., 2014) where P is the average total impact pressure, ρ is the flow density,
 190 v is the velocity, and h is the flow depth. The deposition depth of the debris flow was obtained by
 191 field investigation, while the velocity was calculated using the method outlined in Table 1. The
 192 maximum flow depth and velocity of the flood were extracted from the HEC-RAS model. A
 193 nonlinear regression analysis was conducted using a logarithmic form expression to relate the
 194 vulnerability to the intensity parameters of the hazard.
 195

196 4 Results

197 4.1 Hazard cascade

198 The debris flow event was triggered by a short-term heavy rainfall with 100 years return period.
199 According to the precipitation data from two automated stations located 10 km away, the 24-hour
200 cumulative rainfall from 8:00 on 30 August was approximately 82.8 mm. The rainfall data extracted
201 from the Global Precipitation Measurement (GPM) rainfall product in the Heixiluo Gully showed
202 that the rainfall started on 29 August at 22:00 and lasted until 6:00 on 31 August with a cumulative
203 amount of 147.2 mm. The hourly rainfall increased to 5.18 mm at 19:30 on 30 August, which
204 triggered the debris flow due to the approximately accumulated 61.4 mm of rainfall. The debris
205 flow lasted approximately 40 minutes, and the rainfall intensity reached 6.63 mm/h (Fig. 2). Heavy
206 rainfall caused flooding in the Yanrun Hydrometric station (located 15 km upstream from the study
207 area), resulting in a peak discharge of 893 m³/s (He et al., 2020), which was nearly nine times the
208 average discharge of the Niri river.

209 The debris flows firstly transported approximately 1,050,000 m³ of sediment to the Niri River,
210 forming a temporary debris dam. The debris flow swept away the railway bridge that crossed the
211 gully mouth and impacted the national road across the river. It also destroyed the buildings close
212 to the gully mouth and those on the opposite bank of the main river. Approximately 40 minutes
213 later, the debris flow dam was breached, triggering a high-magnitude flash flood that damaged the
214 national road and buildings near the altered flooding path (Fig.3).

215

216

Figure 2 Hourly and cumulative rainfall on 29, 30, and 31 August 2020 extracted from the Global

218

219 **Figure 3** Illustration of the hazard cascade process: (a) the normal flow of river flow before the occurrence
 220 of debris flow; (b) debris flow blocks the river, creating a dammed lake that destroys the railway, roads, and
 221 buildings; (c) the dammed lake bursts, causing a flood that damaged and the road and buildings

222 **4.2 Dynamic characteristics of the debris flow**

223 Samples of debris particles smaller than 10 cm were taken from three locations (see Fig. 4). The
224 particle size distribution of the debris flow samples is presented in Fig. 5. The calculated bulk
225 density of the debris flow is 1.825 g/cm³, which indicates a viscous debris flow (Kang et al., 2004).

226

227 **Figure 4** Distribution of river and debris flow channel sections and debris flow sampling locations.

228

229 **Figure 5** Particle size distribution of debris flow samples.

230 The debris flow destroyed the Chengdu-Kunming railway bridge situated at the gully mouth and
231 had a flow depth of approximately 4.7 m and a section area of approximately 188 m². The estimated

232 peak discharge at the gully mouth using Kang's equation (1987) was 1871 m³/s, which resulted in
233 a high impact pressure of 223 kPa.

234 The temporal distributions of the maximum depth and velocity of the debris flow are presented
235 in Fig. 6. Majority of buildings close to the river channel and debris flow channel were buried by
236 the debris flow. The debris flow lasted approximately 40 minutes and transported great volume of
237 sediment downstream. The deposition zone extended from the gully mouth to the floodplain of the
238 Niri River, covering a length of 320 m. The deposition area obtained from the simulation is 0.15
239 km², which is close to the area measured from the UAV image, approximately 0.16 km². The
240 thickness of the sediment deposits ranged from 5 m to 15 m, with an average value of 7 m. Fig. 7
241 shows that the debris flow buried one floor of Building 3 and nearly two floors of Building 4
242 (locations indicated in Fig. 6). The simulated maximum depths at Buildings 3 and 4 are 3.2 m and
243 5.5 m, respectively, close to the actual deposition heights. The debris flow flushed into the main
244 river and blocked the Niri River. The river channel was filled with sediment, which led to the
245 formation of a dammed lake that raised the water level by 7-8 m. After 40 minutes, the unstable
246 dammed lake breached, which resulted in a massive flash flood.

Figure 7 Simulated maximum flow depth of debris flow at the location of Building 3 and Building 4

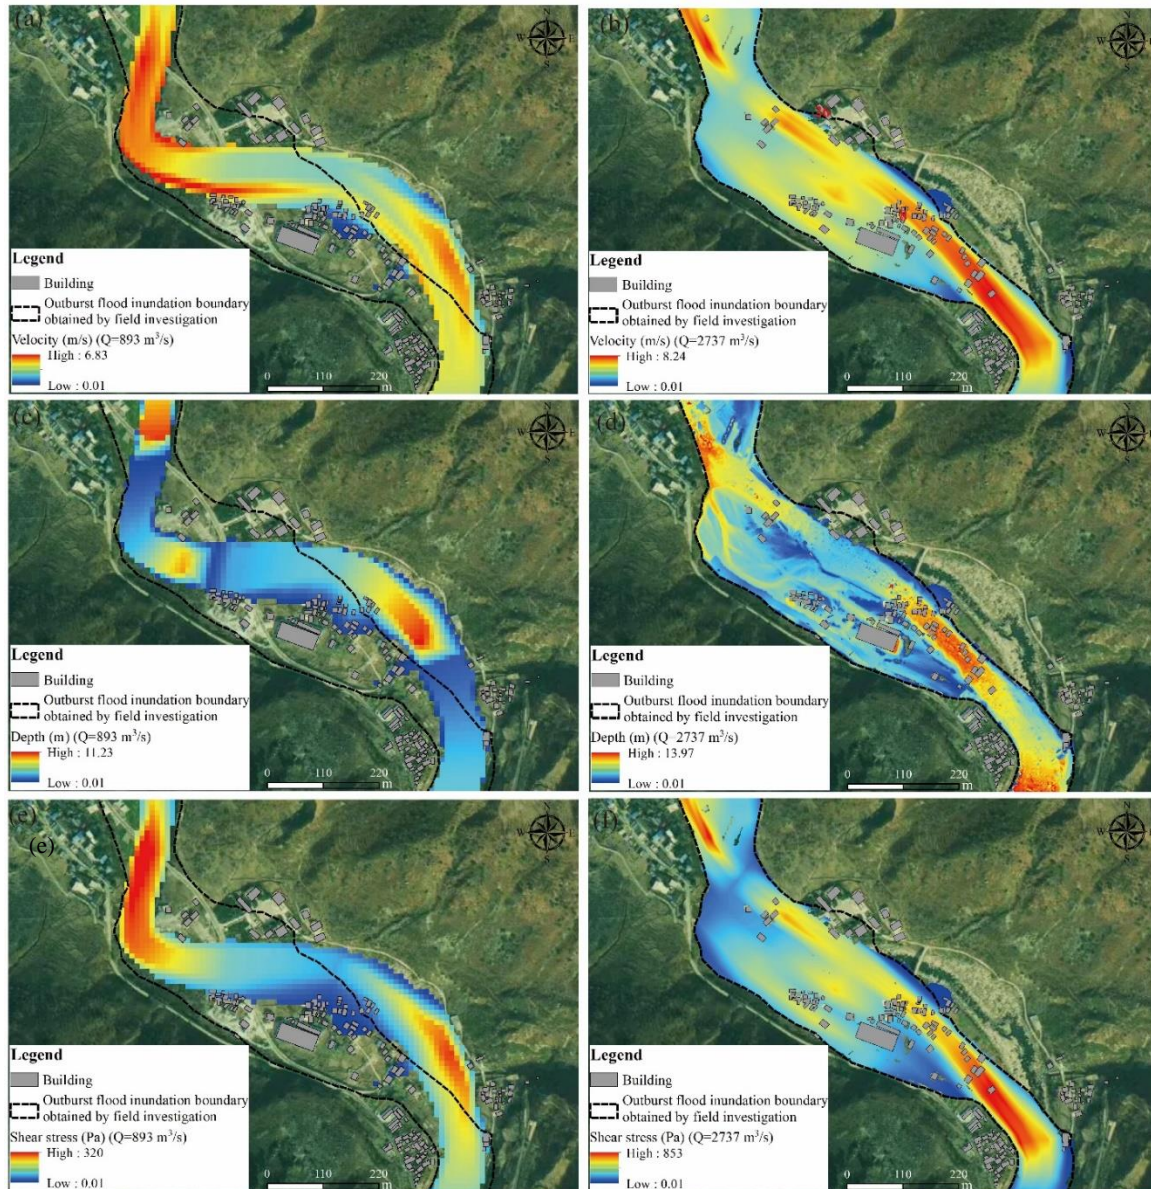

251 4.3 Dynamic characteristics of the outbreak flood

252 The outburst of the debris flow lake caused a sharp increase in flood peak discharge. To analyze

253 the dynamic characteristics of the flood caused by the dam burst, we first used Manning's hydraulic
254 formula for open channel flow (presented in Table 1) to calculate the peak discharge. Then, we
255 selected empirical formulas for dam-burst floods to verify the discharge. A typical section adjacent
256 to buildings damaged by the flood was chosen for the calculation (Fig. 4). Based on flood traces on
257 the outer walls of buildings and the damaged height of buildings, the flood depth was estimated to
258 be 6 m. The cross-sectional area and hydraulic radius were calculated according to the section
259 geometry and channel profile. The channel bed gradient was determined based on the longitudinal
260 channel profile. The resulting peak discharge was 2,737 m³/s. Field investigation revealed that the
261 height of the debris flow dam was approximately 12 m. The volume of the barrier lake was
262 calculated based on the terrain data collected before the disaster. The peak discharge was estimated
263 using the empirical formula proposed by Costa (1985) ($Q_{max} = 1.122V_s^{0.57}$,
264 where V_s is the barrier lake volume), resulting in a flow discharge of 2,273 m³/s with a relative
265 error of 18%, which is comparable to the result obtained by Manning's equation. The temporal
266 distributions of flood depth, velocity, and shear stress in the two scenarios are presented in Fig. 8.
267 The simulated inundation area of the outburst floor is 0.18 km², which is consistent with the field
268 investigation result with an error of 1.1%. The flood completely submerged all buildings on the left
269 bank near the middle of the river channel, and the buildings on the river terrace on the right bank
270 were strongly eroded. The maximum water depth and velocity of the dam-burst flood were 13.96
271 m and 8.24 m/s, respectively, which were 1.24 and 1.31 times higher than those of the ordinary
272 flood, respectively. The maximum depth of the dam-burst flood at locations of Buildings 8 and 26
273 were 6.4 m and 3.7 m, respectively (Fig. 9) (building locations indicated in Fig. 8), which are close
274 to the result obtained by field investigation. The maximum shear stress of the flood in the main
275 channel increased sharply from 320 Pa to 853 Pa, indicating a 2.67-fold increase compared to the
276 ordinary flood. For the ordinary flood scenario, the water depth and velocity were high in the
277 channel and decreased in the floodplain. In contrast, the high velocity and shear stress zones that
278 resulted from the dam-burst flood were mainly distributed in the main channel and along the left
279 bank, indicating that the material deposited by the debris flow and the original river bank are highly
280 susceptible to erosion.

281 The critical shear stress for bedload transport in the gravel-bed river is determined by the equation
282 $\theta = \frac{\tau}{(\rho_s - \rho)gD} = 0.04$, where θ is the critical shear stress, τ is the bed shear stress, ρ_s is the soil mass
283 density, ρ is the water mass density, g is the gravitational acceleration, and D is the sediment
284 diameter (Petit et al., 2015). The dam-burst flood had the potential to transport large boulders up to
285 1.3 m in diameter, while an ordinary flood could only move gravel up to 0.49 m in diameter. Such

286 high shear stress also demonstrated the strong erosional ability of the dam-burst flood, which
287 seriously scoured the debris sediment deposit and original riverbank, transporting coarse gravel and
288 forming a new straight river channel. The new channel is straighter and steeper than the original
289 channel, raising the bed of the Niri River by 1-17 m and burying buildings up to 1 km downstream
290 of Heixluo Gully. The channel length shortened from 1010 m to 842 m, and the channel gradient
291 increased from 1.71% to 2.72%. The change in the river channel led to an inundation area that
292 deflected to the left. Buildings built on the original left riverbank were first impacted by debris flow
293 and subsequently destroyed by the flood. The river terrace on the original right bank was strongly
294 eroded by the flood, leading to the collapse and demolition of buildings. Five river sections (Section
295 1 to Section 5) were selected to analyze the terrain changes (see Fig. 4). From Section 1 to Section
296 3, the main channel varied from the right bank to the left bank with a distance between 40 m and
297 100 m, the average width of the new river channel was 50 m, and the vertical distance between the
298 new riverbed and floodplain was 11.23 m. In Section 5, the channel migrated from the left bank to
299 the right bank due to the severe erosion of the original river terrace and had a maximum depth of
300 10 m (Fig. 10). The channel width increased to approximately 100 m, and the channel depth
301 decreased to less than 5 m.

313 **4.4 Damage patterns of buildings**

314 Nearly 70% of buildings were destroyed by the hazard chain. The evolution of this hazard
315 cascade occurred in two phases. First, the debris flow blocked the main river and formed a barrier
316 dam and dammed lake, which was, second, followed by the outburst of the lake that led to the
317 subsequent flooding and inundation. During the first phase, a significant amount of sediment was
318 transported by the debris flow to the confluence area and deposited in the river channel, which
319 formed a barrier lake with a volume of 857,504 m³. The barrier lake breached completely only
320 approximately 40 minutes later, leading to a highly energetic flood that caused serious erosion of
321 the riverbank and the formation of the outburst flood, a new straight river channel.

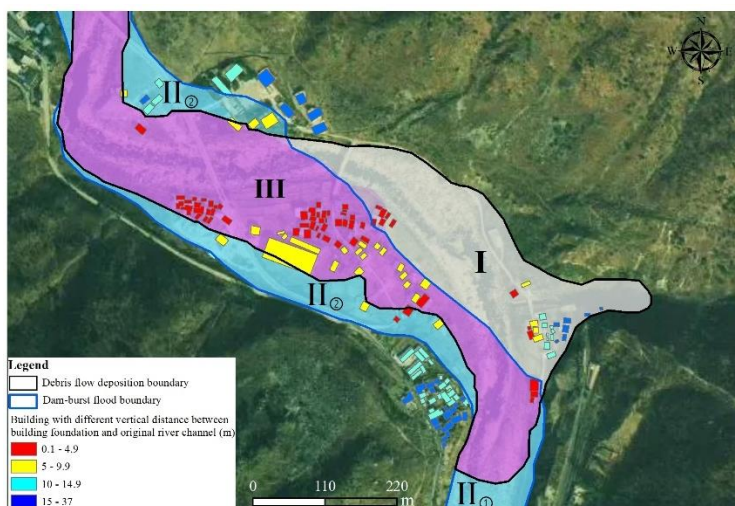

322 Fig. 11 illustrates the boundary of debris flow deposition and dam-burst flood inundation. The
323 debris flow deposition boundary was determined by the simulation. Flooding boundary was
324 obtained by combining the results of the HEC-RAS simulation with field survey data. The
325 confluence area was heavily impacted by the debris flow, resulting in the transportation of a
326 significant amount of solid materials over an area of 0.189 km². As a result, the majority of the
327 village's buildings were inundated by the debris flow. The dam-burst flood caused serious damage
328 to buildings by flushing a large volume of debris flow sediment and riverbank material downstream.

329 Three hazard zones are identified based on the boundary of the debris flow and dam-burst flood,
330 as shown in Fig. 11 and Fig. 12. The damage patterns of buildings in the different hazard zones can
331 be classified into three categories, namely, (I) buildings only buried by debris flow; (II) buildings
332 only inundated by dam-burst flood; and (III) buildings sequentially buried by debris flow and
333 inundated by dam-burst flood. Zone (I) is situated near the Heixiluo gully mouth, where the debris
334 flow transported a large volume of sediment and seriously eroded the sidewall and bed of the
335 channel, expanding the channel's width from 10 m to 40 m. All buildings were inundated by
336 sediment to a depth of over 6 m.

337 Zone (II) is subdivided into two subzones, Zone (II) ① and Zone (II) ②, based on the spatial
338 location. Zone (II) ① is situated in the upstream reach of the Niri River, near the debris flow dam,
339 and is mainly inundated by the static water of the dammed lake (Fig. 12(b)). Zone (II) ② lies on the
340 right bank of the downstream reach of the Niri River, outside the debris flow fan. The original right
341 riverbank in Zone (II) ② was a terrace 10 m high that was severely scoured by the highly energetic
342 flood with a shear stress greater than 450 Pa. The entire terrace was cut off, and a new channel was
343 formed across the middle area (Fig. 12(c)). The erosion area on the river terrace measures
344 approximately 1800 m² with a length of 300 m and a width of 60 m. Two buildings situated on the
345 upper part of the river terrace collapsed and disintegrated due to the impact of the flood (part (a) in
346 Fig. 12(d)). A three-story building was partially destroyed due to foundation erosion. The buildings

347 on the lower part of Zone (II) ② were simultaneously buried by the sediment transported by floods
348 and inundated by floodwater (part (b) in Fig. 12(d)).

349 Zone (III) is primarily located on the left bank of the original river and the lower part of the
350 debris flow fan. The original river channel is filled with debris up to a depth of 10 m. The debris
351 flow transported sediment across the raised riverbed into villages and formed a slope that was high
352 on the right and low on the left in the confluence area. Then, the flood breached the debris flow
353 dam and severely eroded the deposited debris and the original floodplain surface, resulting in a new
354 straight channel. The buildings on the left bank of the river, which were buried by the debris flow,
355 were sequentially impacted by the dam-breach flood. The flood heavily damaged buildings near
356 the new river channel and floodwater from the channel was observed to always inundate the
357 buildings. Notably, the boundaries of the different damage zones are not static. The extent of the
358 damage zone is not the same for other confluence areas; it is determined by the dynamic
359 characteristics of hazards and is also influenced by the local terrain.

360
361 **Figure 11** Inundation boundary of debris flow and dam-burst flood and spatial division of the hazard zone
362 based on building damage patterns: (I) buried by debris flow; (II) inundated by dam-burst flood; (III)
363 buried by debris flow and the inundated by dam-burst flood.

364 A total of 110 buildings in the village were impacted by the multi-hazards, accounting for 69.2%
365 of the total buildings. Among them, 70 buildings located in Zone (III) were impacted by the debris
366 flow and flood in succession, which accounted for 44.0% of the total buildings. In contrast,
367 buildings destroyed by the debris flow in Zone (I) and dam-burst flood in Zone (II) accounted for
368 only 18.2% and 6.9% of the total buildings, respectively (Table 4). Overall, the number of buildings
369 within the debris flow deposition boundary and flood inundation boundary is 99 and 81,
370 respectively, accounting for 62.2 % and 50.9% of the total buildings in the village.

371 The impact force of fluvial sediment transport is greatly influenced by the relative distance of
372 buildings to channels (Wei et al., 2022). Buildings that are close to the channel are always more

373 vulnerable to damage than those located farther away from the river. During the hazard cascade, a
 374 total of 81 buildings in Zone (II) and Zone (III) were impacted by the dam-burst flood (Fig. 12).
 375 To assess the influence of building distance from the river channel, we analyzed the vertical
 376 distances between the damaged building foundation and the original river channel based on pre-
 377 event terrain (Table 5). We found that 51.8% of all damaged buildings were within 5 m of the
 378 channel, while 18.2% of all damaged buildings were between 5 m and 10 m of the original channel.
 379 Buildings that were located at distances greater than 10 m only accounted for 6.3% of the total
 380 damaged buildings. In contrast, the average vertical distance of undamaged buildings was 15.3 m,
 381 with a minimum value of 11.4 m.

390

4.5 Vulnerability analysis of the buildings

391

Most of the buildings in the village were completely buried by sediments or collapsed with no visible remains. To construct vulnerability curves, 27 damaged buildings with brick-concrete structures located in the three hazard zones were selected (Fig. 12(c), Fig. 13). Of these, 6 buildings were located in Zone (II), and the rest were distributed throughout Zone (III).

395

The building characteristics and hazard intensity are presented in Table 6. In Zone (III), buildings located near the debris flow dam (such as buildings 1, 2, and 3) were first buried by the debris flow and then inundated by water from the dammed lake for 40 minutes. These buildings were then impacted by the dam-burst flood. Additionally, buildings near the new river channel suffered greater impact pressure than other buildings. For example, the residual broken structures of buildings 5 and 6 were heavily damaged by the direct impact of the flood in the vertical direction. The walls of the two buildings were severely abraded by impact pressures of 75.1 kPa and 59 kPa, respectively. Additionally, the foundations of the two buildings were partially scoured by floods with high shear stresses of 562 Pa and 553 Pa, respectively.

404

Buildings located in Zone (II) were only severely impacted by the dam-burst flood. For instance, the foundation of the three-story school building (building 26) was severely eroded by the flood to a scour depth of 1 m, and the floors on the right collapsed. There was no evidence on the walls of the building that the debris flow had abraded the structure. The velocity and shear stress of the flood in this location were 4.4 m/s and 463 Pa, respectively. Buildings 23-25, which were close to the new river channel, were thoroughly buried by the sediment transported by the flood and inundated by floodwater.

410

26	3.7	5.3	46.2	0.9	II
27	4.5	4.4	41.4	1	II

414 The vulnerability curve in Zone (II) and Zone (III) was developed by summing up the damage
415 caused by the multiple hazards and impact pressure (Fig. 14). Logistic functions were proposed
416 separately for the two hazard zones, and the corresponding determination coefficient (R^2) and root
417 mean square error (RMSE) were also obtained. The determination coefficients of the two regression
418 curves in Zone (III) have a higher R^2 . The RMSEs of the curves in Zone (II) and Zone (III) are 0.66
419 and 0.55, respectively. The correlation between vulnerability and inundation depth in the two zones
420 is shown in Fig. 15, with an R^2 lower than impact pressure ($R^2=0.55$ for Zone (II) and $R^2=0.45$ for
421 Zone (III)). Building vulnerability increases with increasing hazard intensity, and the trend is similar
422 in the two zones. The impact pressure thresholds for Zones II and III, where vulnerability is equal
423 to 1, are 84 kPa and 116 kPa, respectively. For the same impact pressure and inundation depth, the
424 damage to buildings in Zone (II) is greater than that in Zone (III).

425

Figure 14 Proposed vulnerability functions based on the impact pressure in Zone (II) and Zone (III).

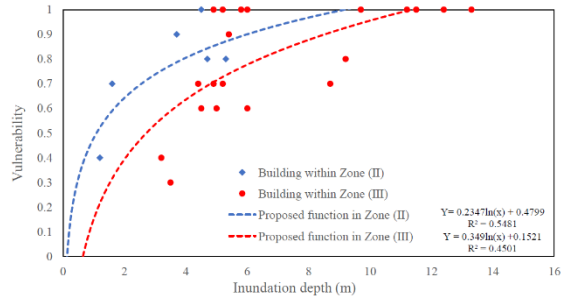

Figure 15 Proposed vulnerability functions based on the inundation depth in Zone (II) and Zone (III).

426 The vulnerability curves proposed for Zone (II) and Zone (III) were compared to the three
427 functions used in debris flow risk assessment (Fig.16, Fig.17). The functions developed by [Quan](#)
428 [et al. \(2011\)](#) and [Kang et al. \(2016\)](#) were calculated based on damage done to brick masonry and
429 nonreinforced concrete structures that had been impacted by the debris flows in South Korea and
430 Italy, respectively. The vulnerability curve proposed by [Zhang et al. \(2018\)](#) was developed for
431 buildings with brick-concrete structures from the Zhouqu debris flow event in China. The slope of
432 the two proposed vulnerability curves based on impact pressure is smaller than those of the three
433 curves. When the impact pressure is less than 20 kPa, the proposed curves show a similar increasing
434 trend compared to the three functions. However, when the impact pressure is greater than 20 kPa,
435 the slope of the two proposed vulnerability curves is much smaller than those of the three curves.

436 For the curves based on inundation depth, when the depth is less than 1.5 m, the slope is steeper
 437 than that of [Quan et al. \(2011\)](#) and [Zhang et al. \(2018\)](#) and slower than that of [Kang et al. \(2016\)](#).
 438 When the depth is greater than 2 m, the damage increases slower than the curves of [Quan et al.](#)
 439 [\(2011\)](#) and [Zhang et al. \(2018\)](#). This disparity may be attributed to the different damage patterns
 440 and structures of the buildings in this study. The three vulnerability functions were generated for a
 441 single debris flow event, whereas the mechanisms by which buildings impacted by floods fail are
 442 not the same when those buildings are subjected to a debris flow. The structures of most buildings
 443 in the study area are tougher than those in the three events, and nearly half of the buildings had
 444 been recently built by a more professional construction team. For example, the newly built four
 445 building 7 was not completely damaged by hazard cascade under impact pressures greater than 63.5
 446 kPa.

Figure 16 Comparison of the building vulnerability functions with the impact pressure functions proposed by [Quan et al. \(2011\)](#), [Kang et al. \(2016\)](#), and [Zhang et al. \(2018\)](#).

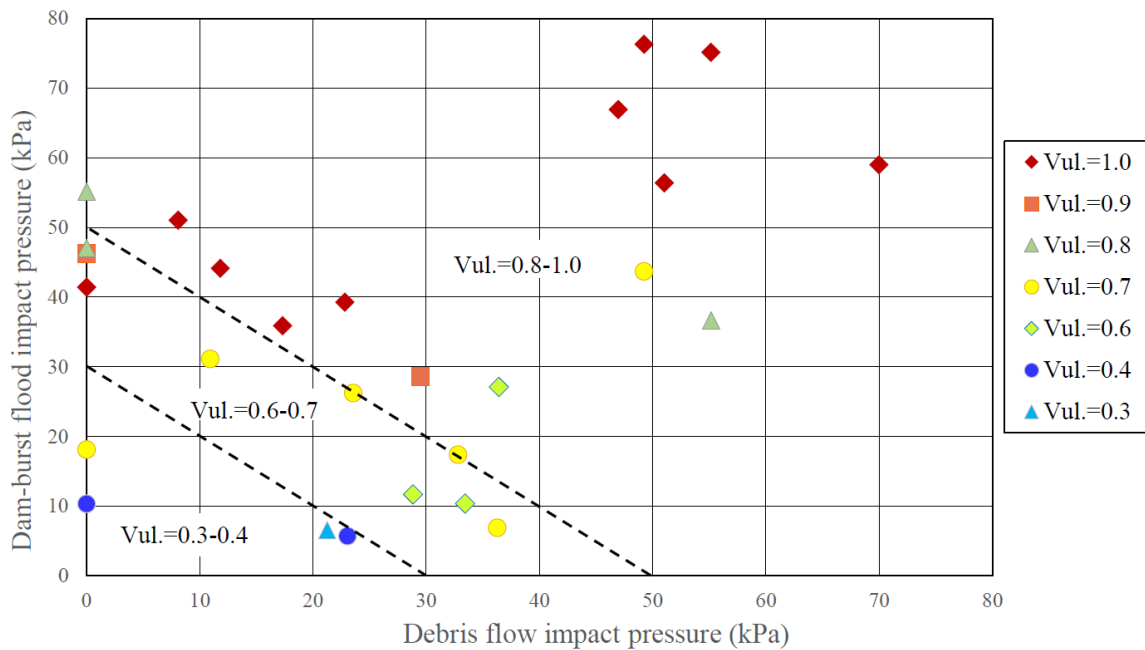

Figure 17 Comparison of the building vulnerability functions with the inundation depth proposed by [Quan et al. \(2011\)](#), [Kang et al. \(2016\)](#), and [Zhang et al. \(2018\)](#).

447 The building damage distribution chart shows building damage plotted as a function of debris
 448 flow and flood impact pressure (see Fig. 18). The figure includes aggregated damage to buildings
 449 impacted by the sequentially occurring hazards in Zone (III) and damage caused by a single hazard
 450 in Zone (II). Damage is divided into three categories based on the threshold impact pressure: slight
 451 damage (0.3-0.4), moderate damage (0.6-0.7), and heavy and complete damage (0.8-1.0). Heavy
 452 and complete damage mainly occurs at impact pressures greater than 50 kPa, while slight damage
 453 occurs below 30 kPa. Moderate damage mainly occurs at impact pressures between 30 kPa and 50
 454 kPa. The threshold impact pressure is compared with that proposed by [Hu et al. \(2012\)](#) and
 455 [Zanchetta et al. \(2004\)](#), which were derived from a single debris flow disaster in China and Italy,
 456 respectively. Although the detailed definition of the damage scales differs, the threshold of the
 457 impact pressure for buildings at the slight, heavy, and complete damage scales is generally larger
 458 than that for the brick-concrete structures presented in [Hu et al. \(2012\)](#) and smaller than that for the
 459 reinforced concrete frames also presented in [Hu et al. \(2012\)](#) and the masonry structures with

460 basements presented in Zanchetta et al. (2004). A similar trend for the threshold of the impact
 461 pressure for buildings with a moderate damage scale can be observed.

462
 463 **Figure 18** Accumulation of building damage due to debris flow and dam-burst flood. The damage
 464 distribution is based on the debris flow and flood impact pressure (Vul. refers to vulnerability).

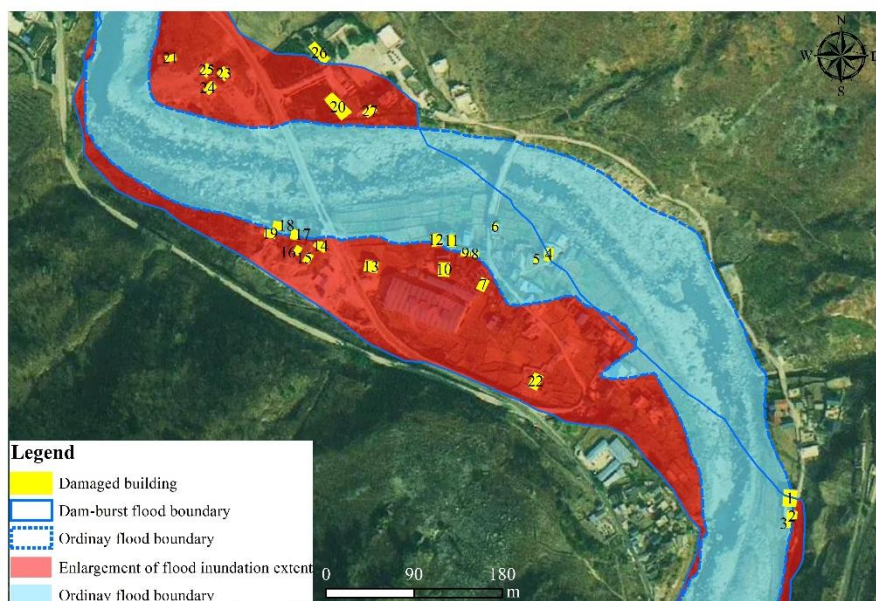

465 The building damage distribution chart remains a valid tool for assessing the vulnerability of
 466 buildings affected by debris flows and flash floods, despite not incorporating all damage ratios.
 467 However, some limitations and uncertainties exist within the vulnerability functions. For instance,
 468 calculating a single average impact pressure value prebuilding for building clusters introduces
 469 uncertainty, as water depth and velocity differ significantly at different sides of the building due to
 470 the shielding effect (Hu et al., 2012; Arrighi et al., 2020). Furthermore, the building's geometry,
 471 direction, orientation, and maintenance condition are not considered in the vulnerability analysis.
 472 The amplification of debris flow damage is due to subsequent flooding in time and space.
 473 Aggregated damage (i.e., damage caused by both debris flows and floods) is applied in the
 474 vulnerability analysis for areas that are successively struck by debris flows and floods. However,
 475 the amplified damage effect of the dam-burst flood on debris flow was not accurately quantified
 476 because of the absence of a database containing information regarding the damage done by the
 477 debris flow before the dam burst. As a result, more detailed data are needed to assess the cumulative
 478 impact of hazard cascades on building vulnerability.

479 **5 Discussion**

480 **5.1 Damage aggravation due to hazard cascade**

481 As a result of the confluence zone's location on a river bend, the dam-burst flood typically flows
482 in a straight direction and creates a new straight channel when the river channel becomes
483 completely blocked. This channel translocation leads to a larger flooded area and causes more
484 severe damage to buildings on the floodplain. The flood inundation zones in the village expanded
485 to 110^5 m^2 , which is up to 4 times the area of an ordinary flood due to flood amplification (Fig. 19).
486 In the expanded inundation zone, 41 buildings, a traffic road spanning 410 m, and farmland with
487 an area of $10 \times 10^4 \text{ m}^2$ were submerged. The buildings located in the middle of the inundation zones
488 suffered the most severe damage due to the floodwater's high scouring capability and sediment
489 transport capacity. Many buildings near the flow collapsed, and most structures were carried away
490 by the water current.

491 Table 7 presents a comparison of the dynamic characteristics and damage increments between
492 ordinary and dam-burst floods in different locations. The damage increment is calculated based on
493 the proposed function in Zone II and is the ratio of the damage caused by the two floods. Buildings
494 4, 5, 6, 9, 11, 18, and 19 were situated close to the new river channel, and the average bed shear
495 stress and impact pressure increased up to 14.2 times and 3.8 times that of an ordinary flood,
496 respectively, due to flood amplification. The average damage to the seven buildings located near
497 the new channel increased by 140% due to the lake created by the debris flow barrier.

498
499

Figure 19 The inundation extent of ordinary floods and dam-burst floods.

500 **Table 7** Comparison of dynamic characteristics and degree of damage between ordinary floods and dam-
 501 burst floods in different locations

Location	The ratio of dam-burst flood to ordinary flood				
	Depth	Velocity	Bed shear stress	Impact pressure	Damage degree
Building 4	1.5	1.5	8.3	1.9	1.2
Building 5	0.8	2.0	13.1	2.0	1.2
Building 6	2.3	1.7	11.8	2.5	1.3
Building 9	15.0	3.2	33.8	11.2	2.4
Building 11	4.6	2.2	19.0	4.9	1.6
Building 18	2.6	1.1	6.2	1.5	1.1
Building 19	18.6	1.3	7.4	2.7	1.3
Average value	6.5	1.9	14.2	3.8	1.4

502 **5.2 The implication of hazard mitigation**

503 In recent years, the hazard cascade of debris flows and outburst floods has become more frequent
 504 in high mountain regions due to the impact of climate change and earthquakes (Chen et al., 2022).
 505 The damage caused by the primary debris flow can be intensified and enlarged due to the successive
 506 dam-burst flood.

507 Risk assessment for debris flow-outburst flood hazard cascades is crucial to mitigate the damage
 508 posed to structures in the confluence zone. Risk analysis should incorporate both the debris flow
 509 initiation mechanism and the mechanism that generates the dam-burst flood (Chen et al., 2022). A
 510 detailed investigation should be conducted for the exposed elements in the confluence zone and
 511 both the upstream and downstream reaches of the river. Based on the disaster transformation
 512 process and the failure mechanisms of structures, hazard zones should be identified, and
 513 corresponding disaster reduction measures should be developed (Cui and Guo, 2021). Moreover,
 514 specific structural measures are urgently needed. First, engineering measures should be
 515 implemented in the watershed to mitigate debris flows (Cui and Lin, 2013). Second, buildings
 516 should not be constructed near debris flow gullies, and new buildings should be built on elevated
 517 ground or at certain elevations above the ground (Attems et al., 2019). Third, deflection walls
 518 should be considered and constructed in villages susceptible to debris flows to protect entire
 519 buildings (Wang et al., 2022), and flood protection walls should be built along the main river to
 520 protect the entire flood-prone village.

521 This study presents a comprehensive analysis of the damage to buildings resulting from a large-
 522 scale debris flow and outburst flood hazard cascade. The study develops building vulnerability in
 523 different areas of the confluence zone, which is useful for building risk assessment and management
 524 along the riverbank. However, some uncertainties and limitations are involved in vulnerability

525 analysis. Firstly, the study did not consider the building's physical characteristics, such as shape,
526 orientation, and maintenance condition. Secondly, in the area affected by the two hazards, the
527 capacity of buildings first damaged by debris flow had declined, leading to a higher failure
528 probability under the impact of sequential flood (Luo et al., 2020). The study analyzed the
529 buildings' structural vulnerability based on debris flows and dam-break flood separately, and did
530 not consider the building response to the primary debris flow or quantify the cumulative effect of
531 the debris flow and the dam-break flood (Luo et al., 2023). A physics-based vulnerability model is
532 required to quantify the dynamic evolution of building vulnerability.

533 **6 Conclusions**

534 Buildings in the confluence zone of a debris flow-prone catchment and along a main river
535 channel are highly vulnerable to a debris flow-dam-burst flood hazard cascade. Assessing building
536 damage is essential for risk mitigation and resilient construction. However, research concerning
537 building damage mainly focuses on a single debris flow or flash flood and fails to consider the
538 different damage characteristics of buildings exposed to both hazards simultaneously. Therefore,
539 studying the characteristics and patterns of building damage in confluence areas can help to develop
540 a reliable vulnerability assessment method. In this study, we investigate the dynamic characteristics
541 of the hazards and damage patterns of the 2020 Heixiluo debris flow and dam-burst flood disaster.
542 We draw the following conclusion:

543 1. The dam-burst flood, which had a peak discharge of 2,737 m³/s, seriously eroded the debris
544 flow fan and formed a new straighter and steeper channel. The maximum estimated velocity was
545 8.24 m/s, and the bed shear stress reached 853 Pa. The flood's inundation extent in the confluence
546 zone was expanded by a factor of 4, and the impact pressure increased up to 6.8 times due to flood
547 amplification. The average damage to buildings near the new river channel was 1.4 times more
548 intense due to the hazard cascade.

549 2. The damage patterns of the buildings were classified into three types: (I) buried by primary
550 debris flow, (II) inundated by secondary dam-burst flood, and (III) buried by debris flow and
551 inundated by dam-burst flood sequentially. The spatial division of hazard zones can be applied to
552 the selection of building sites and the planning of structural measures in the confluence area.

553 3. The vulnerability curves show a similar increasing trend with impact pressure and inundation
554 depth in Zones II and III, and the threshold of the impact pressures in Zones II and III where
555 vulnerability is equal to 1 is 84 kPa and 116 kPa, respectively. A vulnerability assessment chart
556 was developed, and three categories, namely, slight damage (0.3-0.4), moderate damage (0.6-0.7),
557 and heavy and complete damage (0.8-1.0), were identified. Heavy damage occurs at an impact

558 pressure greater than 50 kPa, while slight damage occurs below 30 kPa. Moderate damage occurs
559 at an impact pressure between 30 kPa and 50 kPa.

560 4. Some uncertainties and limitations are involved in vulnerability analysis. The building's
561 physical characteristics, such as shape, orientation, and maintenance condition, should be
562 considered for the vulnerability analysis. Further investigation and research are recommended to
563 explore the cumulative effect of multiple hazards on building vulnerability. Despite the deficiencies,
564 vulnerability curves, and assessment charts are valuable for analyzing the risk posed by debris flow
565 hazard cascades within the confluence zone.
