13 **Abstract:** Investigating the processes governing drought propagation under a changing environment is essential
14 for advancing drought early warning and reducing socio-economic risks. Currently, few studies have analyzed
15 the effects of meteorological factors and watershed characteristics on drought propagation based on non-
16 stationary drought indices. In this paper, the probabilities and thresholds of meteorological drought to
17 hydrological drought propagation were calculated using the non-stationary drought index constructed using the
18 Generalized Additive Model for Location, Scale, and Shape (GAMLSS) model and the Copula function to assess
19 the influence of large-scale climatic indices, meteorological elements, and watershed characteristics on the
20 propagation characteristics of seasonal droughts. The results showed that non-stationary drought indices that
21 incorporate meteorological factors tended to have a better performance than standardized drought indices. Under
22 the combined influence of large-scale climatic indices, temperature, specific humidity, and wind speed, the
23 propagation probabilities became larger especially during spring and winter in the upstream and midstream
24 regions of the Luanhe River Basin, China, with the propagation thresholds in winter significantly increases by
25 0.1-0.2. These mean that hydrologic droughts are more likely to be triggered. Furthermore, the spatial variability
26 of drought propagation is further influenced by watershed characteristics, including the slope and leaf area index,
27 which collectively alter runoff generation processes.

28 **Keywords:** Climate change; Watershed characteristics; Drought propagation; Luanhe River basin

29 **1. Introduction**

30 As one of the major climate problems, meteorological drought poses a serious threat to the ecological
31 environment and social economy (Wang et al., 2022; Hao et al., 2019; Kumar et al., 2019). In a drought event,
32 meteorological drought often occurs first and insufficient precipitation leads to hydrological drought or
33 agricultural drought through the hydrological cycle (Han et al., 2019; Zhang et al., 2022; Zhong et al., 2020).
34 This process of meteorological drought triggering hydrological or agricultural drought is called inter-type
35 drought propagation (Zhang et al., 2021; Wossenyeleh et al., 2021; Apurv and Cai, 2020; Jehanzaib et al., 2020).
36 After suffering from numerous drought disasters, it is widely recognized that the impact of drought on human
37 life can be reduced by investigating the propagation of droughts. (Pandey et al., 2022; Dehghani et al., 2019; Le
38 et al., 2016).

39 Drought is often studied based on drought indices, and the choice of drought index is crucial for
40 characterizing regional drought (Mahmoudi et al., 2019; Tao et al., 2021; Xu et al., 2021). Some drought indices:
41 the Standardized Precipitation Index (SPI), the Standardized Precipitation Evapotranspiration Index (SPEI), the
42 Standardized Runoff Index (SRI) and the Standardized Soil moisture Index (SSI) are used to describe the
43 drought characteristics of a region (McKee et al., 1993; Vicente-Serrano et al., 2010; Shukla and Wood, 2008; Xu
44 et al., 2021). In recent years, scholars have made a lot of efforts to examine drought propagation characteristics,
45 employing a wide range of analytical tools including both statistical analyses and model simulations. Such as the
46 Copula models (Wu et al., 2022; Wang et al., 2022; Guo et al., 2020), **Markov models** (Yeh and Hsu, 2019;
47 Vorobevskii et al., 2022), and Variable Infiltration Capacity (VIC) model (Bhardwaj et al., 2020; Lilhare et al.,
48 2020). Wang et al. (2022) analyzed the propagation probability characteristics of meteorological drought to
49 hydrological drought in the Yiluo River Basin based on the Copula function. Sattar et al. (2020) assessed the
50 propagation probability of meteorological drought to different categories of hydrological drought in the Han
51 River basin using Markov Bayesian Classifier and conditional probabilities. Bhardwaj et al. (2020) assessed
52 drought propagation characteristics in India based on the SPI and VIC models.

53 Some studies have shown that under the dual influence of climate change and human activities, the
54 spatiotemporal evolution characteristics of drought are difficult to analyze (Wu et al., 2022; Jehanzaib et al.,
55 2020; Zhou et al., 2019). Therefore, scholars analyzed the factors that affect the propagation of droughts around
56 the world (Li et al., 2019b). For instance, Jehanzaib et al. (2020) and Peña-Gallardo et al. (2019) have found that
57 climate type, climate change, catchment characteristics, and other factors can affect the propagation of drought.

58 Ding et al. (2021) showed the effect of climate on drought propagation by comparing the differences in
59 propagation time from meteorological drought to hydrological drought in different climatic regions of China.
60 Guo et al. (2021) assessed the impact of large reservoirs on propagation by comparing differences in drought
61 propagation characteristics before and after reservoir construction.

62 Under the influence of climate change and human activities, precipitation and runoff series show significant
63 non-stationarity and uncertainty, and drought studies become more complex and urgent (Wang et al., 2015; Wang
64 et al., 2020; Jehanzaib et al., 2023). Therefore, researchers incorporate non-stationarity into drought studies
65 through more appropriate analytical tools. The GAMLSS model is one of the commonly used methods.
66 Previously, researchers mostly used the non-stationary drought index constructed based on the GAMLSS model
67 to assess the impacts of climate change, human activities, and other factors on a single drought, indicating that
68 the non-stationary drought indices have a better performance than the stationary drought index in drought
69 research (Shao et al., 2022; Wang et al., 2023). Since then, the non-stationary drought indices have been
70 gradually applied to the study of drought propagation. Das et al. (2022) constructed non-stationary
71 meteorological and hydrological drought indices using large-scale climatic factors and regional meteorological
72 elements as covariates for precipitation and runoff, respectively, and assessed the impact of external drivers on
73 drought propagation characteristics. Overall, fewer studies incorporate non-stationary drought indices into
74 drought propagation.

75 As the main source of water supply for the Beijing-Tianjin-Tangshan area, the Luanhe River Basin is
76 responsible for multiple tasks such as urban water supply, and industrial and agricultural water supply. Frequent
77 droughts in recent years have not only affected the supply of regional water resources but also had a serious
78 impact on the ecological environment. Therefore, an in-depth understanding of the evolution pattern and impact
79 mechanism of drought is of great significance to the rational allocation of water resources and sustainable
80 development of the basin. According to some recent studies, there are non-stationary characteristics in the
81 precipitation series and the runoff series of the Luanhe River Basin (Li et al., 2019a; Li et al., 2020) and the
82 occurrence of drought in Luanhe River Basin may be related to some large-scale climatic indices (Wang et al.,
83 2018; Li et al., 2015; Wang et al., 2016). Wang et al. (2016) pointed out that the Atlantic Multi-Year Oscillation
84 (AMO) has a significant effect on drought in the Luanhe River Basin. In addition, meteorological factors are also
85 important in influencing droughts in the basin. Chen et al. (2022) pointed out that the increase in temperature
86 will lead to more frequent hydrological droughts in the Luanhe River Basin in the future. Previous studies on the
87 Luanhe River Basin have focused on examining the effects of large-scale climatic factors on a single type of

88 drought, with few assessments of the effects of large-scale climatic indices and regional meteorological elements
89 on drought propagation (Li et al., 2015; Wang et al., 2015; Li et al., 2024).

90 Although some progress has been made in the study of drought propagation, there are few studies
91 considering the impact of changing environments. Furthermore, spatial and temporal differences in drought
92 propagation are strongly related to watershed characteristics. To evaluate the influence of external driving factors
93 on drought propagation, NSPI and NSRI were constructed based on GAMLS framework with climate indices
94 and meteorological factors as covariates. The propagation probability and propagation threshold of
95 meteorological drought to hydrological drought were calculated by Copula model under stationary and non-
96 stationary conditions in different seasons, respectively. The effects of climate change on drought propagation
97 were quantified at a seasonal scale, and the impacts of watershed characteristics on drought propagation were
98 explored.

99 **2. Study area and data**

100 The Luanhe River is the second largest river in Hebei Province, China, and its geographical location is
101 shown in Fig.1 (a). The area of the basin is about 44750 km², with an average width of 90km from east to west
102 and a length of 500km from north to south, including a mountainous area of 43940 km² (Li et al., 2024). There
103 are obvious differences in physical and geographical conditions, and the topography of the whole basin is high in
104 the northwest and low in the southeast.

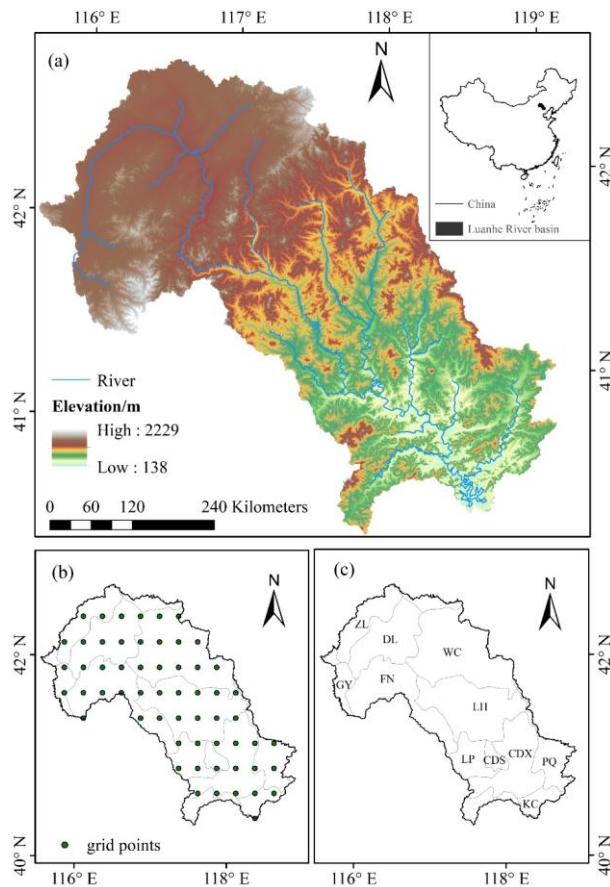

105 The surface is flat and the river valley is wide and shallow in the Luanhe River basin. The climate
106 difference between the north and south of the Luanhe River basin is obvious. The annual mean temperature
107 ranges from 1 to 11°C, while the July mean temperature ranges from 17 to 25°C (Gao et al., 2024). Affected by
108 the continental monsoon climate, the basin has four distinct seasons of precipitation, with an average annual
109 precipitation of 400~800mm, of which summer precipitation accounts for 67%-76% of the total annual
110 precipitation; spring and autumn account for about 9% and 15% respectively; and winter precipitation accounts
111 for only about 2% (Li et al., 2023). The climate type changes from cold temperate arid and semi-arid climate to
112 warm temperate semi-humid climate.

113 With global climate change, drought disasters in the Luanhe River Basin are becoming increasingly
114 frequent, causing serious losses to the region's ecology and socio-economy. According to historical records, the
115 main drought events in the Luanhe River Basin occurred in 1961, 1963, 1968, 1972, 1980-1984, 2000, 2007, and

116 2009. The cumulative economic losses caused by drought disasters in the basin during the period from 1960 to
117 2010 exceeded 13 billion yuan. **Under the influence of climate change and human activities, the characteristics**
118 **of drought propagation in the basin become more complex.**

119 In this paper, the large-scale climatic indices (abbreviated as CI) Nino3.4, Atlantic Multidecadal Oscillation
120 (AMO), Southern Oscillation Index (SOI), Pacific Decadal Oscillation (PDO), Arctic Oscillation (AO), North
121 Atlantic Oscillation (NAO) and North Pacific (NP) data are derived from the National Oceanic and Atmospheric
122 Administration (NOAA) (<http://www.esrl.noaa.gov/psd/data/climateindices>) (1960-2014). The average monthly
123 precipitation, temperature, wind speed, specific humidity, evapotranspiration, and runoff datasets are available at
124 a grid resolution of 0.25° Lat \times 0.25° Lon and are obtained from Global Land Data Assimilation System (GES
125 DISC Dataset: GLDAS Noah Land Surface Model L4 monthly 0.25 x 0.25 degree V2.0 (GLDAS_NOAH025_M
126 2.0)). The grid-wise analysis is carried out at a resolution of 0.25° Lat \times 0.25° Lon over the Luanhe River which
127 includes 58 grid points (Fig.1 (b)). Leaf area index of 0.25° spatial resolution was derived from the Advanced
128 Very High Resolution Radiometer (AVHRR) Global Inventory Modeling and Mapping Studies (GIMMS)
129 LAI3g version 2 (https://daac.ornl.gov/cgi-bin/dsviewer.pl?ds_id=1653) (1981–2015). The slope data is
130 extracted from 90 m resolution DEM data, and the data set is provided by Geospatial Data Cloud site, Computer
131 Network Information Center, Chinese Academy of Sciences (<http://www.gscloud.cn>). In addition, based on
132 county-level administrative divisions, this study divides the research area into 11 sub-regions, namely ZL, DL,
133 GY, FN, WC, LH, LP, CDS, CDX, PQ, and KC (Fig.1 (c)). Based on geographical features, the watershed is
134 divided into three parts: upstream, midstream, and downstream. The upstream region includes ZL, DL, GY, FN,
135 and the northern part of WC; the midstream region includes the southern part of FN, the southern part of WC,
136 LH, and LP; and the downstream region includes CDS, CDX, PQ, and KC.

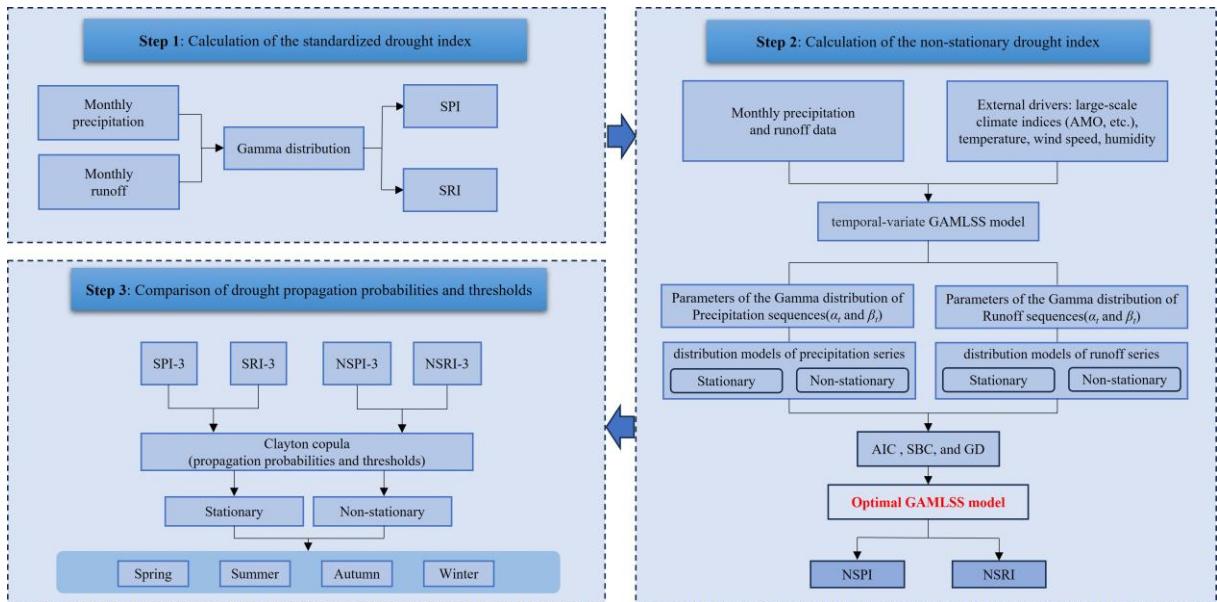

137

138 **Figure 1 The geographical location of the Luanhe River Basin (a), and the grid points contained in the**
 139 **watershed boundaries (b), 11 subregions contained in the watershed (c)**

140 **3. Methods**

141 The current study aims to assess the impact of external drivers on drought propagation based on the
 142 GAMLSS model, in particular, the probability and threshold of drought propagation in different seasons. Fig.2
 143 summarizes the steps of the current study. First, the standardized drought indices SPI and SRI were calculated
 144 based on monthly-scale rainfall and runoff. Then, the non-stationary drought indices NSPI and NSRI were
 145 calculated using the large-scale climate indices and regional meteorological factors as covariates of the non-
 146 stationary Gamma distribution parameters of the rainfall and runoff series, respectively. Finally, based on the
 147 copula function, the drought propagation probability and threshold under stationary and non-stationary
 148 conditions were calculated, and the impact of external driving factors on the propagation of meteorological
 149 drought to hydrological drought was analyzed and quantified.

150 **Figure 2 Flowchart of this study**

151 **3.1 The calculation of drought index**

152 **3.1.1 Stationary Model**

153 Based on precipitation data, the SPI is constructed using hydrological statistical principles and
 154 standardization methods. The index has the advantages of convenient data collection, simple calculation, and is
 155 suitable for multi-spatiotemporal scale calculations. Suppose that the precipitation series x at a certain time
 156 scale satisfies the probability density function of Gamma distribution $f(x)$:

$$157 \quad f(x) = \frac{x^{\alpha-1} e^{-x/\beta}}{\beta^\alpha \Gamma(\alpha)} \quad (1)$$

158 In the formula, α and β are shape and scale parameters ($\alpha > 0, \beta > 0$) and they are treated as constants in
 159 the GAMLSS framework. The cumulative probability of precipitation is as follows:

$$160 \quad F(x) = \int_0^x f(x) dx \quad (2)$$

161 The corresponding SPI is obtained by normalizing the cumulative probability $F(x)$ of each item. The
 162 cumulative probability normalization method is based on the inverse normal function algorithm proposed by
 163 Abramowitz and Stegun. (1965).

164 If $0 < F(X) \leq 0.5$:

$$165 \quad k = \sqrt{\ln \left[\frac{1}{F^2(x)} \right]} \quad (3)$$

$$166 \quad \text{SPI} = -k - \left(\frac{c_0 + c_1 k + c_2 k^2}{1 + d_1 k + d_2 k^2 + d_3 k^3} \right) \quad (4)$$

167 If $0.5 < F(X) \leq 1$:

169

$$k = \sqrt{\ln \frac{1}{[1-F(x)]^2}} \quad (5)$$

170

$$SPI = k - \left(\frac{c_0 + c_1 k + c_2 k^2}{1 + d_1 k + d_2 k^2 + d_3 k^3} \right) \quad (6)$$

171 Here: $c_0 = 2.515517$, $c_1 = 0.802853$, $c_2 = 0.010328$, $d_1 = 1.4132788$, $d_2 = 0.189269$ and $d_3 = 0.001308$.

172 As a drought index that can effectively and accurately describe the hydrological drought characteristics of
173 the basin, SRI can be calculated by replacing the precipitation sequence with the runoff sequence and the
174 calculation method of SRI is similar to that of SPI. Table 1 shows the drought class classification (Kolachian and
175 Sagafian, 2021).

176 **Table 1 Drought class classification and corresponding SPI values and SRI value**

SPI\SRI value	Class
> -0.5	Normal
-0.5 to -1.00	Mild
-1.00 to -1.50	Moderate
-1.50 to -2.00	Severe
≤ -2.00	Extreme

177 **3.1.2 Nonstationary Model**

178 Generalized Additive Models for Location, Scale, and Shape (GAMLSS) proposed by Rigby and
179 Stasinopoulos. (2005) can flexibly analyze non-stationary time series, more details of GAMLSS are available in
180 Rigby and Stasinopoulos. (2005). In recent years it has often been applied to capture non-stationary in series
181 such as precipitation and runoff. The non-stationary model presented in this paper is based on the study by Das
182 et al. (2022). To better study the seasonal characteristics of drought and capture the changes in meteorological
183 elements caused by seasonal climate change, this paper chooses the drought index on a 3-month time scale to
184 analyze the propagation characteristics of drought, and the GAMLSS model is used to construct a non-stationary
185 model for the analysis of precipitation and runoff changes. By incorporating large-scale climate factors as
186 covariates, a non-stationary meteorological drought index is constructed and used to capture the non-stationary
187 characteristics of precipitation series in the basin. In this paper, based on the calculation principle of the
188 standardized drought index, the non-stationary Gamma distribution of precipitation and runoff is constructed
189 based on the GAMLSS model. The correlated climate variables are selected from these large-scale climate
190 factors (e.g., AMO, SOI, PDO, AO, NAO, and NP). To capture the non-stationary characteristics of the basin
191 runoff sequence, the non-stationary hydrological drought index (NSRI) was constructed. **The meteorological**

variables (wind speed, temperature, and specific humidity) were considered as covariates for the non-stationary model of hydrological drought index. The semi-parametric additive model formula used in this study is as follows:

$$g_1(\alpha_t) = \sum_{j=1}^{j_k} h_{jk}(c_{jk}) \quad (7)$$

$$g_2(\beta_t) = \sum_{j=1}^{j_k} h_{jk}(c_{jk}) \quad (8)$$

Where $g_1(\alpha_t)$ and $g_2(\beta_t)$ are the link functions, which are determined by the domain of the statistical parameter, namely, if the domain of the distributed parameter α_t and β_t are $\alpha_t, \beta_t \in R$, the link functions are $g_1(\alpha_t) = \alpha_t$ and $g_1(\beta_t) = \beta_t$, if $\alpha_t, \beta_t > 0$, then $g_1(\alpha_t) = \ln \alpha_t$ and $g_2(\beta_t) = \ln \beta_t$. The h_{jk} represents the dependence function of the distribution parameters on the covariates c_{jk} . The parameter coefficients and model residuals are estimated by RS algorithm, and whether the model residuals approximately satisfy the normal distribution is analyzed, and the optimal fitting distribution is selected by AIC (Akaike Information Criterion), SBC (Schwarz Bayesian Criterion), and GD (Global Deviance).

3.2 The Copula model

In multivariate drought probability analysis, the Copula function is an effective tool for constructing multivariate joint drought distributions with multiple characteristics based on the univariate distribution and the linkage structure between random variables. The equation is expressed as follows:

$$F(x, y) = C(F_X(x), F_Y(y)) \quad (9)$$

where C is the two-dimensional Copula function, $F(x, y)$ is a joint distribution function, $F_X(x)$ and $F_Y(y)$ are the marginal distribution functions of two random variables X and Y , respectively. Before establishing the joint distribution, the marginal distribution of the random variables needs to be determined, and in this study, the normal distribution is used as the marginal distribution of the meteorological drought index and hydrological drought index series. Droughts are usually extreme climatic events, precipitation shortages and other extreme conditions, which are statistically manifested in the behavior of data tails, and Clayton Copula can effectively capture the tail correlation between variables, which is especially significant in the research of drought. Therefore, Clayton Copula is used to construct the joint distribution between meteorological drought and hydrological drought indices in this paper (Guo et al., 2021; Zhang et al., 2022; Zhang et al., 2023). Based on the Copula model, the conditional probabilities are calculated as follows (Liu et al., 2022):

$$P[Y \leq y | X \leq x] = \frac{P(Y \leq y, X \leq x)}{P(X \leq x)} = \frac{C(F_X(x), F_Y(y))}{P(X \leq x)} \quad (10)$$

Here, $P(X \leq x)$ denotes the cumulative probability of $X \leq x$. In this paper, with the meteorological drought index as the condition and the hydrological drought index as the target, then $P[Y \leq y | X \leq x]$ denotes the conditional probability of occurrence of hydrological drought under different meteorological drought conditions.

224 The drought propagation threshold (PT) is commonly defined as the severity of the meteorological drought
225 that is most likely to cause hydrological drought, i.e., the SPI critical threshold. In this paper, the conditional
226 probability density of SPI was calculated for each scenario in the interval of -3 to 3 at an interval of 0.01, and
227 when $SRI \leq -0.5$, the SPI value corresponding to the maximum point of the conditional probability density is the
228 meteorological drought threshold that triggers hydrological drought (Zhou et al., 2022).

229 To visualize more intuitively the difference between meteorological drought to hydrological drought
230 propagation thresholds under non-stationary and stationary condition, the change rate of drought propagation
231 thresholds was calculated with the following equations:

$$232 \quad R_c = \left| \frac{T_n - T_s}{T_s} \right| \times 100\% \quad (11)$$

233 where T_n and T_s the thresholds of meteorological drought to hydrological drought propagation under non-
234 stationary conditions and stationary conditions, respectively.

235 4. Results

236 4.1 Selection of Climate Indices

237 Pearson correlation test can be used to test whether there is a correlation between two sample sequences that
238 follow a normal distribution. Usually, there is more than one climate factor affecting meteorological drought
239 (Gao et al., 2020). In this paper, to select the relevant climate variables linked with meteorological drought in the
240 Luanhe River basin, the Pearson correlation test was carried out to test the correlation between cumulative
241 precipitation series at different time scales K (K = 1, 3, 6, 12, 24 months) and the *CI* with a lead time M (M = 0,
242 1, 2, 3 months) for all regions of the basin. The standardized climatic index series were averaged over a period
243 (*AP*) of 1, 3, 6, 12, and 24 months (*CI-n*: *CI* with *AP=n*). To analyze the seasonal drought characteristics of the
244 basin, we selected the significant climate indices for the cumulative precipitation series on a three-month time
245 scale. According to the correlation test results, AMO-1 and AMO-24 have higher correlation than other climate
246 indexes, so AMO-1 and AMO-24 are selected as the covariates of rainfall. AMO-1 and AMO-24 with a lead time
247 of M=0 months were selected as covariates for the precipitation series and the test results are shown in Fig.3. In
248 addition, the correlation between AMO-1, AMO-24 and precipitation series with lag time of 1, 2 and 3 months
249 from 1961 to 2014 is shown in the supplementary document (Tables S1-S6).

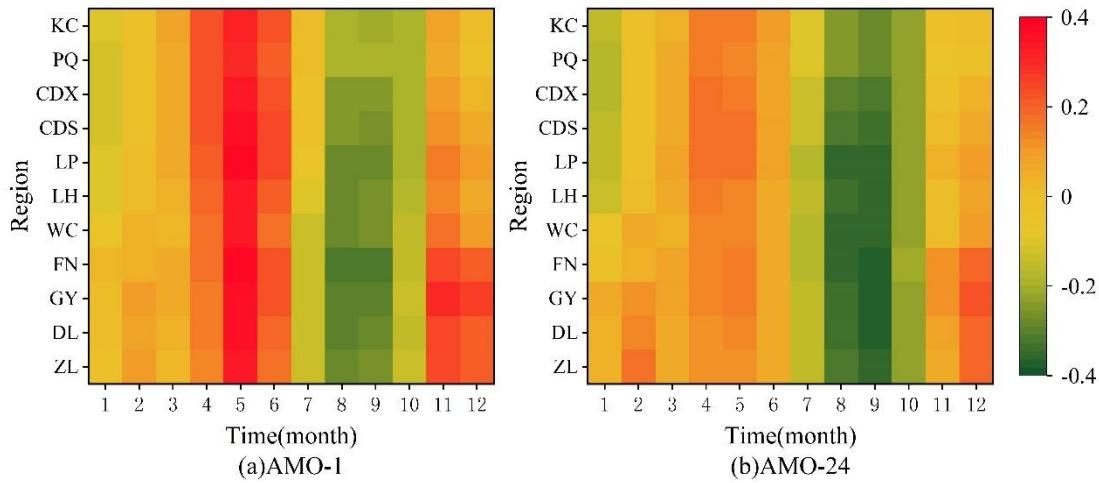

Figure 3 The correlation between AMO and precipitation series during 1961-2014

Trends of temperature, wind speed, and humidity in different seasons were calculated by the Mann-Kendall (M-K) trend analysis method in the watershed (Mann, 1945; Cheng et al., 2023). The results are presented in Table 2. When the absolute value of Z is greater than 1.96, it indicates that the series shows a significant level of $p < 0.05$. The temperature shows a significant upward trend in four seasons. Wind speed shows a decreasing trend in spring and summer and an increasing trend in autumn and winter. Relative humidity showed an increasing trend in spring, summer, and winter, and a decreasing trend in summer.

Table 2 Trends of temperature, wind speed, and specific humidity in different seasons during 1961-2014
(The bold numbers represent the series shows a significant trend.)

	Z			
	Spring	Summer	Autumn	Winter
Temperature	4.55	4.37	4.13	3.66
Wind speed	-0.03	-4.21	0.12	0.58
Specific humidity	1.29	-0.07	1.10	2.61

4.2 Preference of GAMLSS model

4.2.1 The simulation of precipitation series

GAMLSS framework was used to model the precipitation in each region of the watershed. To analyze the seasonal drought characteristics of the region, the SPI was calculated for 3-month time scales in this article. According to the correlation test results, AMO (AP=1 and AP=24) was selected as the significant CI for non-stationary modeling of precipitation. Seven different situations were considered according to the structure of the GAMLSS model (the model types are shown in Table 3). The AIC, SBC, and GD were used to select the optimal

267 model, taking the CDS region as an example. The results of model preferences for the precipitation series are
 268 shown in Table 4.

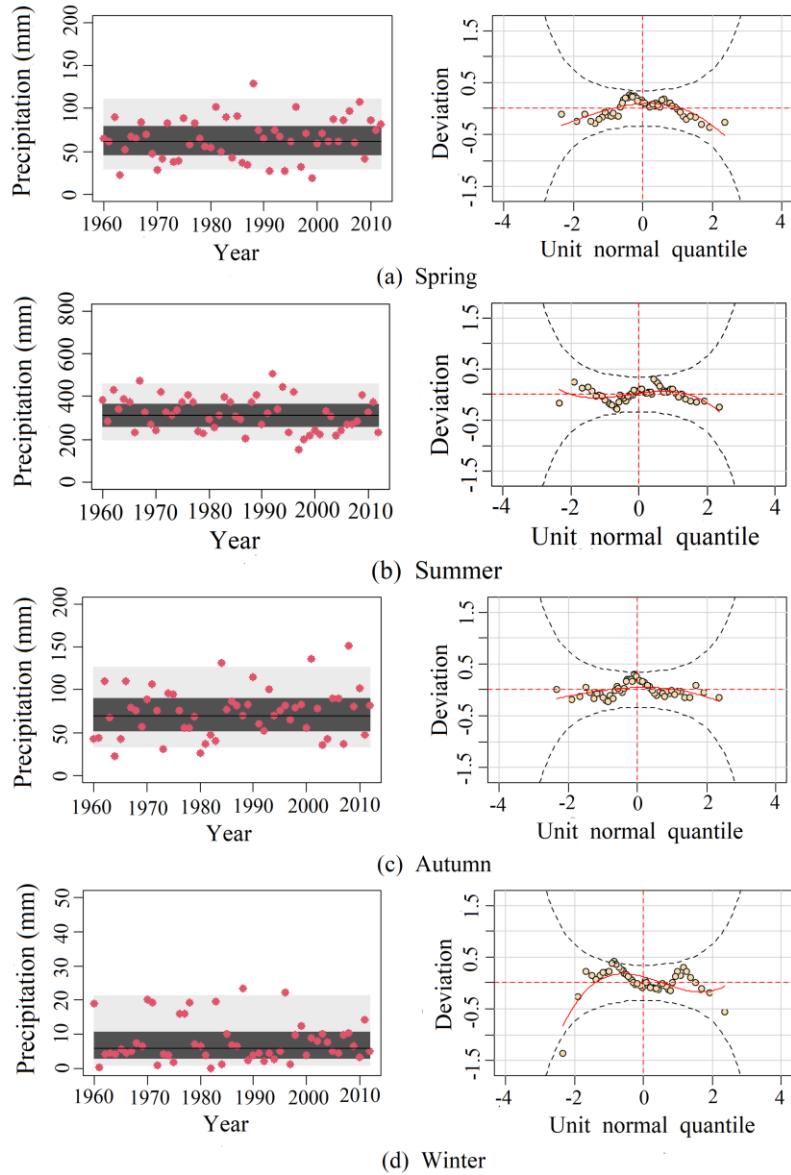

269 **Table 3 Different model situations considered for precipitation simulation (CI-n: CI with the AP=n month)**

Model	Parameters	
	α_t	β_t
Mod 1	~1	~1
Mod 2	~1	~AMO-1, AMO-24
Mod 3	~ AMO-1, AMO-24	~1
Mod 4	~1	~AMO-24
Mod 5	~AMO-24	~1
Mod 6	~1	~AMO-1
Mod 7	~AMO-1	~1

270 As can be seen from Table 4, for the non-stationary models of precipitation in the CDS region, among all
 271 the models with climate index as covariates, Mod7 has the best performance in spring, with the AIC, SBC, and
 272 GD of 494.1, 500.0 and 488.1 respectively. The optimal model in summer was Mod5, the AIC, SBC, and GD
 273 were 625.8, 631.7, and 619.8. In autumn, the optimal model was Mod1, the AIC, SBC, and GD were 505.8,
 274 509.7, and 501.8. Mod2 had the best performance in winter, with the AIC, SBC, and GD of 322.5, 330.4, and
 275 314.5. The results of the estimated model parameters of the precipitation in the CDS region are shown in Table 5.
 276

277 **Table 4 AIC, SBC, and GD of the different models of precipitation in the CDS region (the Bold indicates
 the optimal model)**

Model	Spring			Summer			Autumn			Winter		
	AIC	SBC	GD									
Mod 1	498.2	502.2	494.2	626.8	630.7	622.8	505.8	509.7	501.8	325.3	329.3	321.3
Mod2	501.7	509.6	493.7	629.2	637.1	621.2	509.4	517.3	501.4	322.5	330.4	314.5

279 **Figure 4 Fitting results of four seasons of precipitation series in the CDS region (These red dots represent**
 280 **precipitation observations, light grey areas represent areas between the 5% and 95% centile curves, dark**
 281 **grey areas represent areas between the 25% and 75% centile curves, and black lines represent the median**
 282 **(50%); the black dashed line in the worm plot of the fitted residuals indicates the 95% confidence interval)**

283 To assess the quality of the fitting, Fig.4 provides the simulation of precipitation from the GAMLSS
 284 framework (Taking the CDS region as an example). It can be seen from Fig.4 that the precipitation data values of
 285 the four seasons were basically within the 95% quantile interval, the deviation values in the worm chart were
 286 evenly distributed in the 95% confidence interval, and there was no obvious excess, which indicates that the
 287 residual fitting of the Gamma distribution meets the conditions. In general, the temporal behavior associated with
 288 the data was significant, the results of the model (Fig.4) seem to reproduce the behavior of the data, especially to
 289 capture the large dispersion characteristics of the data.

Table 5 Model parameters estimation results in four seasons in the CDS region

Season	Parameters
Spring	$\alpha_t = \exp(4.17 + 0.13AMO_{t-1})$
	$\beta_t = \exp(-0.98)$
Summer	$\alpha_t = \exp(5.75 - 0.10AMO_{t-24})$
	$\beta_t = \exp(-1.43)$
Autumn	$\alpha_t = \exp(4.29)$
	$\beta_t = \exp(0.40)$
Winter	$\alpha_t = \exp(2.04)$
	$\beta_t = \exp(-0.20 - 0.49AMO_{t-1} + 0.29AMO_{t-24})$

4.2.2 The simulation of the runoff series

For the simulation of runoff, temperature(T), specific humidity(H), and wind speed(W) were considered as covariates of the shape and position parameters of the gamma distribution. Table 6 shows the models for the different combinations of the covariates considered, and taking the CDS region as an example, the optimal results are listed in Table 7.

Table 6 Different model situations considered for runoff simulation

Model		
	α_t	β_t
Mod 1	~1	~1

Mod 13	~T and W	~1

297 **Table 7 AIC, SBC, and GD of the best suitable model of the non-stationary model of runoff in the CDS**
 298 **region**

Season	The optimal model	
Spring	Mod 10	AIC: -70.28 SBC: -60.43 GD: -80.27
Summer	Mod 4	AIC:136.19 SBC:142.10 GD:130.19
Autumn	Mod 3	AIC: -58.67 SBC: -50.79 GD: -66.67
Winter	Mod 3	AIC: -447.77 SBC: -439.89 GD: -455.77

299 The results of the estimated model parameters of the runoff in the CDS region as an example were shown in
 300 Table 8. As seen in Table 8, the main factors affecting the spring runoff series were temperature, specific
 301 humidity, and wind speed, with specific humidity having a greater influence than the other two factors. In
 302 summer, temperature was the main factor influencing the runoff series. In autumn and winter, runoff sequences
 303 were mainly influenced by temperature and specific humidity.

304 **The simulation results of the stationary model and non-stationary model for runoff in the CDS region are**
 305 **shown in Fig.5.** As can be seen from Fig.5, most of the runoff data values (red points) of the four seasons were
 306 located in the light gray area (5% and 95% centile curves), and the data deviations in the worm plots were evenly
 307 distributed in the 95% confidence interval (between the two black ellipses dotted lines), which show that non-
 308 stationary gamma distribution meet the requirements for the fitting of runoff series. In Fig.5, the non-stationary
 309 model showed the time variation characteristics of the runoff series flexibly. Generally, the non-stationary model
 310 can describe the variability of runoff series accurately. In summary, the non-stationary model with temperature,
 311 specific humidity, and wind speed were considered as covariates that can capture the time variation
 312 characteristics of the runoff series.

313 **Table 8 Model parameters estimation results in four seasons of the CDS region**

Season	Parameter
--------	-----------

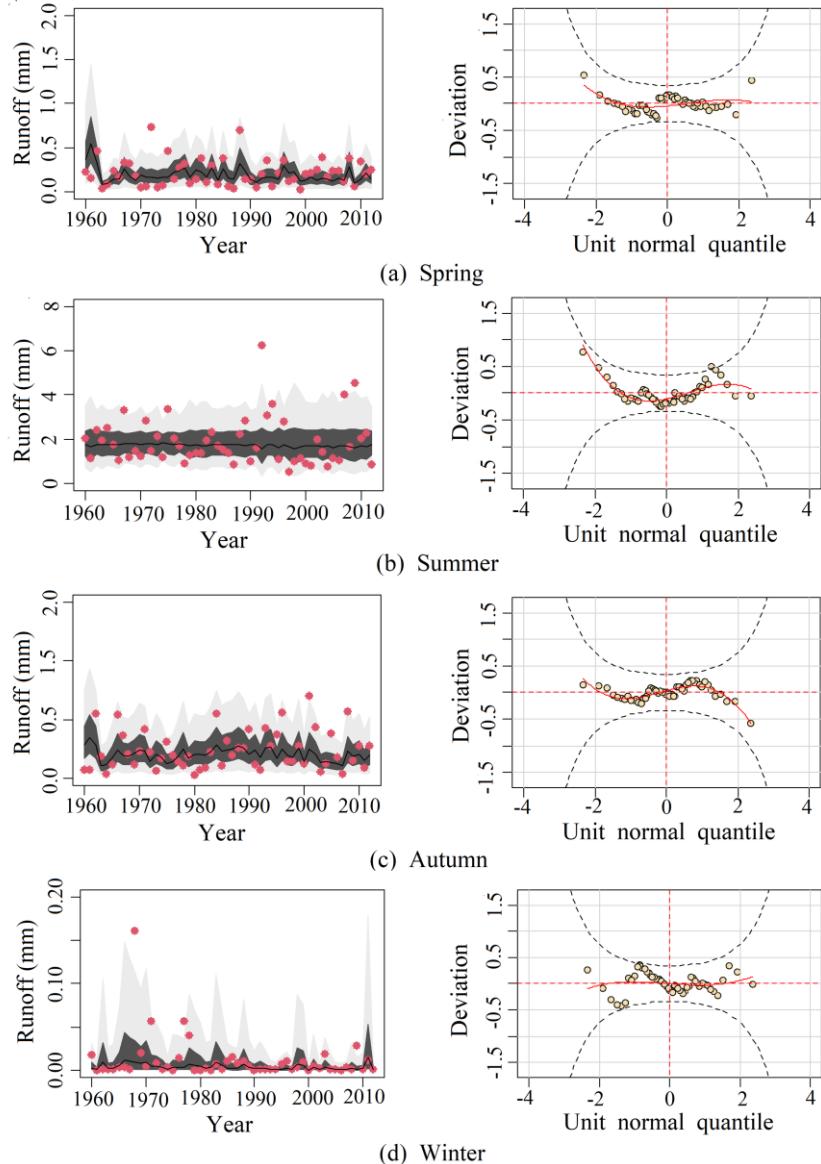

Spring	$\alpha_t = \exp(-1.57 - 0.37T_t + 0.54H_t + 0.28W_t)$ $\beta_t = \exp(-0.42)$
Summer	$\alpha_t = \exp(0.62)$ $\beta_t = \exp(-0.73 + 0.23T_t)$
Autumn	$\alpha_t = \exp(-1.45 - 0.29T_t + 0.48H_t)$ $\beta_t = \exp(-0.41)$
Winter	$\alpha_t = \exp(-4.85 - 1.91T_t + 1.34H_t)$ $\beta_t = \exp(0.48)$

314 The results of the optimal modeling of the non-stationary series for the 11 regional runoffs are presented in
 315 Table 9. Table 9 shows that there are some differences in the optimal models of the non-stationary runoff series
 316 in different regions in different seasons, among which the spatial differences of the optimal models in winter are
 317 the most significant. The optimal models in spring are mainly Mod3 and Mod10, in summer the optimal models
 318 are mainly Mod2, Mod4 and Mod8, in autumn the optimal models are Mod3 and Mod7, and in winter the
 319 optimal models are mainly Mod3 and mod11.

320 **Table 9 Optimal model of non-stationary runoff series in different seasons in each region of the basin**

323 **Figure 5 Fitting results of four seasons of runoff series in the CDS region** (These red dots represent runoff
 324 observations, light grey areas represent areas between the 5% and 95% centile curves, dark grey areas
 325 represent areas between the 25% and 75% centile curves, and black lines represent the median (50%); the
 326 black dashed line in the worm plot of the fitted residuals indicates the 95% confidence interval)

327 **4.3 Calculation of stationary and non-stationary indices**

328 According to the simulation results of the model in Section 4.2, the non-stationary models have better
 329 performance than the stationary models in the simulation of runoff series in all regions. The comparison results
 330 of SRI and NSRI in different seasons in CDS are shown in Fig.6. It can be seen that the distribution of two
 331 indices is generally similar. Furthermore, the climate factors had different impacts on the index in different
 332 seasons, with the smallest impact on summer and the most significant impact on winter.

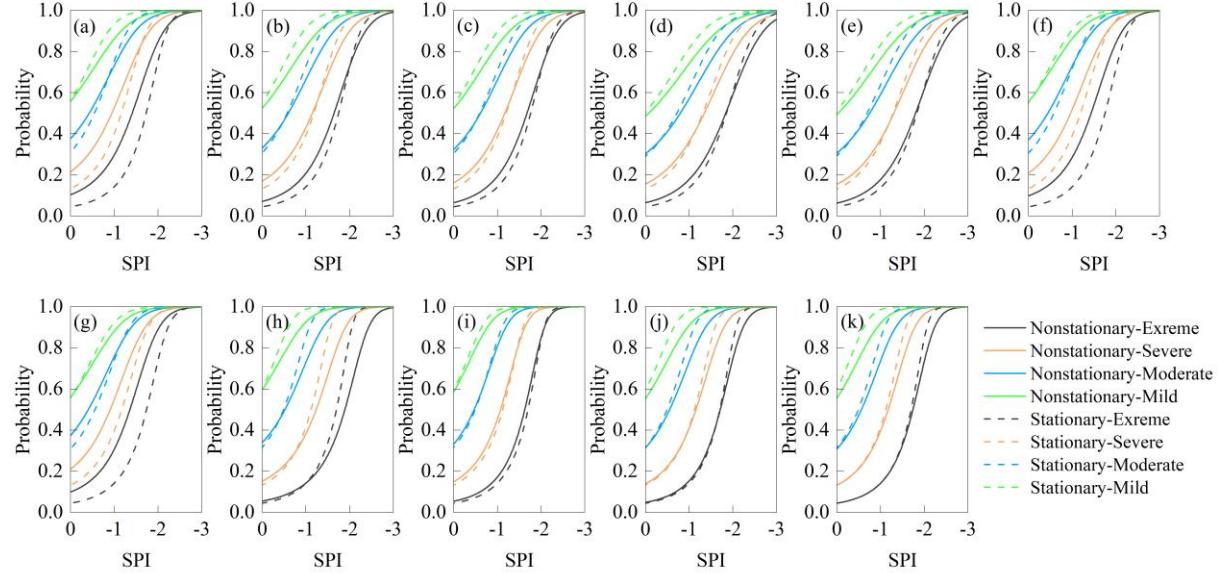

334 **Figure 6 Comparison of SRI and NSRI in different seasons in the CDS region during 1961-2014 (a: Spring;**
 335 **b: Summer; c: Autumn; d: Winter)**

336 **4.4 Drought propagation probability**

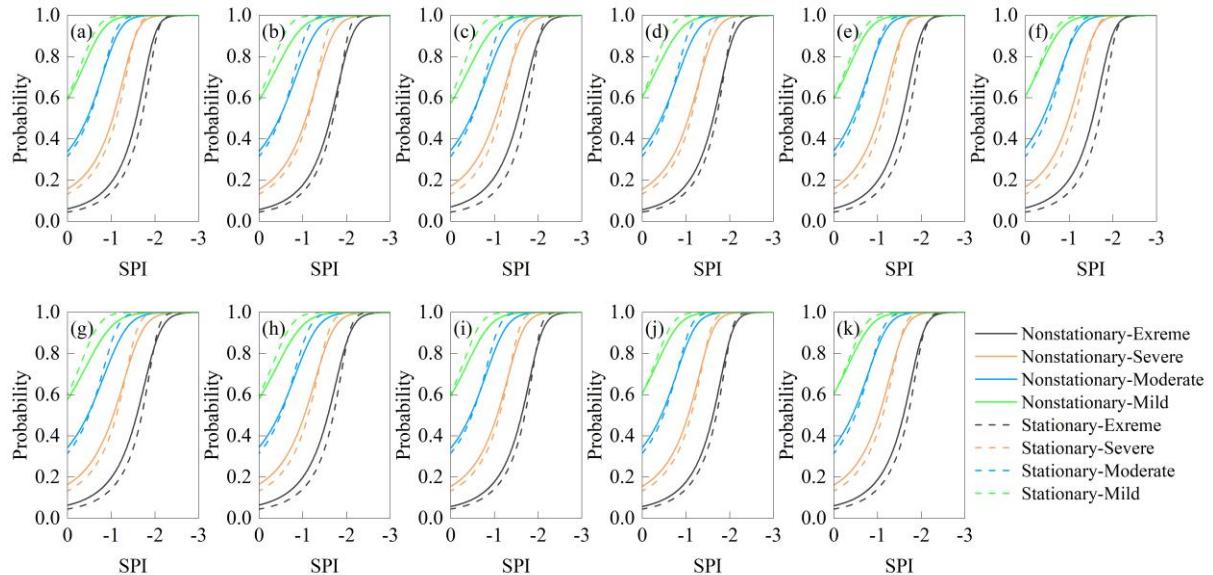

337 Based on the Copula model, the probabilities of meteorological drought propagation to hydrological
 338 drought can be calculated, and the impact of climate change on drought propagation can be analyzed. The
 339 calculated results in different seasons and different regions were shown in Figs.7-10, where the solid and dashed
 340 lines indicate the calculated results of the non-stationarity model and the stationarity model, respectively, and
 341 black, red, blue, and green represent extreme drought, severe drought, moderate drought, and mild drought,
 342 respectively. According to the analysis results in Figs.7-10, the probabilities of the occurrence of hydrological
 343 drought increased with the decrease of SPI, and as the degree of meteorological drought worsened, it might lead

344 to more severe hydrological drought. In addition, the drought propagation probabilities calculated based on the
 345 non-stationarity model were significantly different from those calculated by the stationarity model, and they also
 346 differ in different seasons and regions.

348 **Figure 7 Probability of drought propagation in spring for each region (a: ZL; b: DL; c: GY; d: FN; e: WC;
 349 f: LH; g: LP; h: CDS; i: CDX; j: PQ; k: KC)**

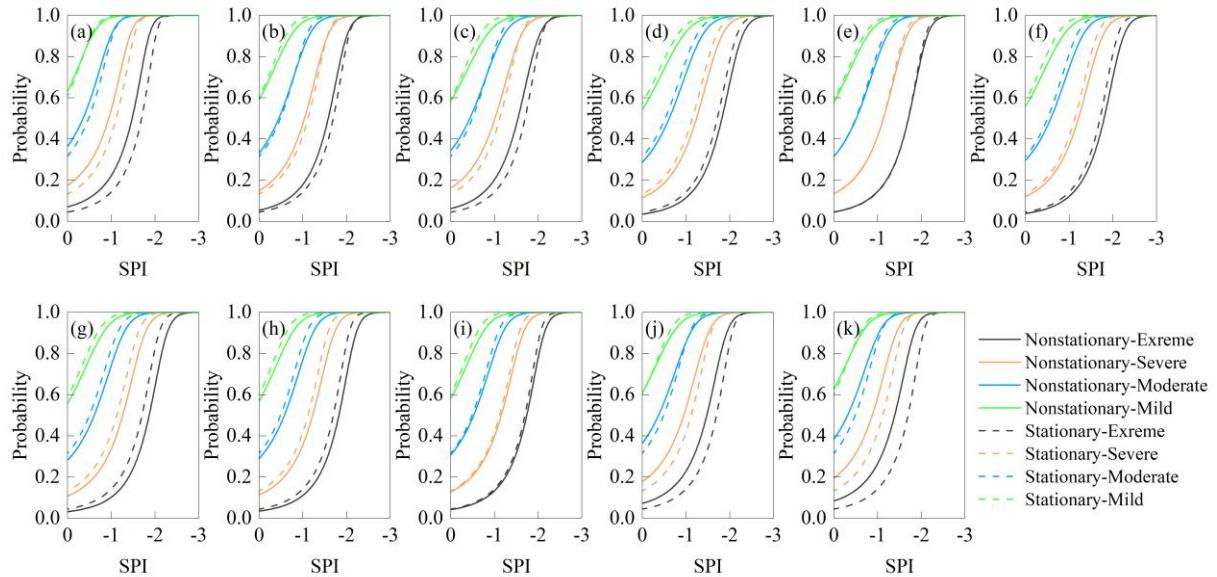

350 Fig.7 shows the calculated results of drought propagation probabilities in spring in 11 regions. In the
 351 upstream (ZL, DL, GY,) and middle regions (WC, FN, LH, LP, and CDS) of the basin, the drought propagation
 352 probabilities calculated by the non-stationary model were significantly different from those calculated by the
 353 stationary model, while the calculated results were relatively close in the downstream areas such as CDX, PQ
 354 and KC. For the upstream and middle regions, under the same meteorological drought conditions, the
 355 probabilities of severe and extreme hydrological drought calculated based on the non-stationary model were
 356 larger than that of the stationary model, while in the downstream area, the probabilities of hydrological drought
 357 calculated by the stationary model were slightly higher than that of the non-stationary model. According to the
 358 modeling structure of the precipitation and runoff sequence in spring in section 4.2, under the combined
 359 influence of climatic factors AMO, temperature, specific humidity, and wind speed, regional hydrological
 360 drought is more likely to occur. In contrast to the stationary conditions, the increase in temperature may be the
 361 main factor that causes the hydrological drought to become more severe in spring.

362 **Figure 8 Probability of drought propagation in summer for each region (a: ZL; b: DL; c: GY; d: FN; e:**
 363 **WC; f: LH; g: LP; h: CDS; i: CDX; j: PQ; k: KC)**

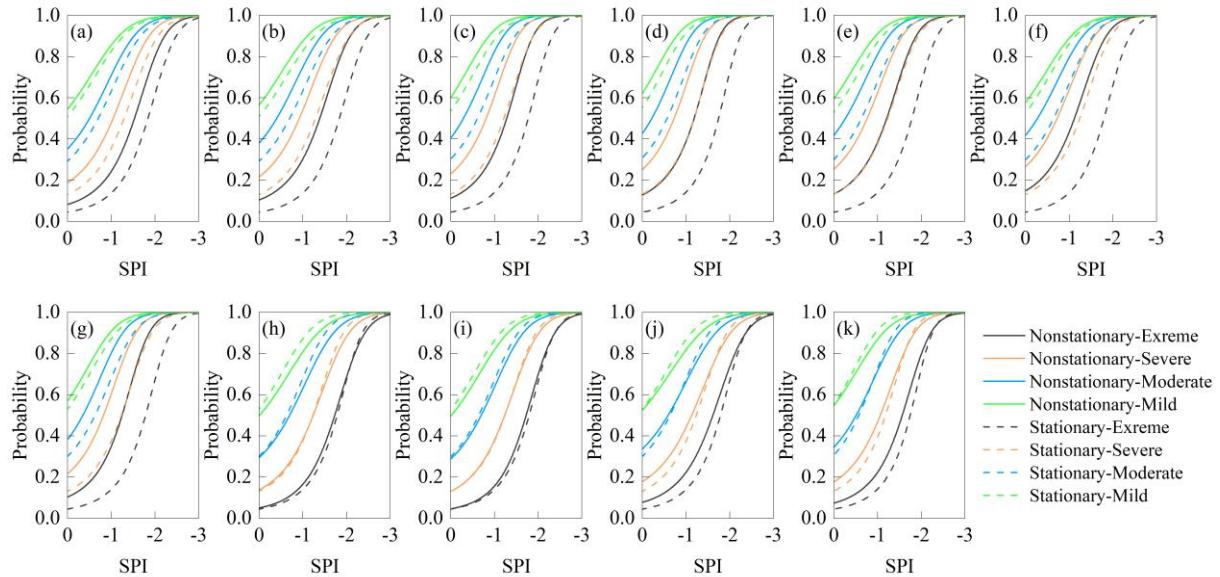

364 In summer (Fig.8), in each region, the difference between the drought propagation probabilities calculated
 365 by the non-stationary model and the results calculated by the stationary model was not significant, and the
 366 probability of occurrence of severe and extreme hydrological droughts calculated by the non-stationary model
 367 was larger. Taking the ZL region as an example (Fig.8(a)), when climate change was not considered, the
 368 probability of severe hydrological drought and extreme hydrological drought was 0.6 and 0.17, respectively.
 369 Under the influence of the changing environment, the probability of causing severe hydrological drought and
 370 extreme hydrological drought was 0.62 and 0.2 respectively. This means that climate changes had little impact
 371 on drought propagation in the basin during the summer when precipitation was abundant. In contrast to the
 372 stationary conditions, the AMO and temperature may be the main climate reasons for the greater probability of
 373 drought propagation in summer (Zhang et al., 2022).

374 Different from spring and summer, in autumn (Fig.9), The probabilities of occurrence of moderate drought
 375 and more severe hydrological droughts calculated by the non-stationary model were larger than those of the
 376 stationary model in the upstream (ZL, DL, and GY) and downstream regions (CDX, PQ, and KC), which
 377 indicated that the propagation of droughts in the upstream and downstream regions was influenced by climate
 378 change significantly. As can be seen from Table 9, specific humidity is the main influence on the differences in
 379 drought propagation in the upstream (ZL, DL, GY, FN, and WC), while drought in the middle and lower reaches
 380 (LH, LP, CDS, CDX, PQ, and KC) is influenced by a combination of temperature and specific humidity.

382
 383 **Figure 9 Probability of drought propagation in autumn for each region (a: ZL; b: DL; c: GY; d: FN; e:
 384 WC; f: LH; g: LP; h: CDS; i: CDX; j: PQ; k: KC)**

385 In winter (Fig.10), the probabilities of occurrence of moderate and more severe hydrological droughts in the
 386 upstream and midstream regions calculated based on the non-stationary model were significantly larger than
 387 those calculated by the stationary model. Taking the WC station as an example, when climate change was not
 388 considered, the probabilities of occurrence of moderate, severe, and extreme hydrological droughts under
 389 moderate meteorological drought conditions were about 0.8, 0.6, and 0.4, respectively, while under the influence
 390 of environmental change, the probabilities of moderate, severe and extreme hydrological droughts were about
 391 0.9, 0.8 and 0.6, respectively. In most of the downstream areas, the difference between the calculation results of
 392 the two models was relatively small. Under the combined influence of AMO, temperature, wind speed, and
 393 specific humidity, the probabilities of drought propagation are increased. In upstream, the increase in wind speed
 394 may be the main climate factors affecting the occurrence of severe drought, and the increase in temperature and
 395 specific humidity may be the main climate factors affecting the occurrence of severe drought in midstream and
 396 downstream regions.

397 **Figure 10 Probability of drought propagation in winter for each region (a: ZL; b: DL; c: GY; d: FN; e: WC; f: LH; g: LP; h: CDS; i: CDX; j: PQ; k: KC)**

398 Comparing the four seasons, the probabilities of occurrence of moderate and more severe droughts were the
 401 lowest in spring, but the highest in winter, this phenomenon was significant under non-stationarity conditions.
 402 Taking the FN region as an example (Fig.7(d)- Fig.10(d)), the probabilities of moderate meteorological drought
 403 propagating as moderate, severe, and extreme hydrological drought in spring under non-stationarity conditions
 404 were close to 0.6, 0.4, and 0.15, respectively, while in winter, the probabilities of propagating as moderate,
 405 severe and extreme hydrological drought under the same meteorological drought conditions were close to 0.9,
 406 0.7 and 0.4, respectively. The reasons for the differences in the probabilities of drought propagation under
 407 stationary and non-stationary conditions are complex. On the one hand, non-stationary models capture changes
 408 caused by interannual variability, and on the other hand, they are affected by AMO, temperature, wind speed, and
 409 relative humidity. There may be some differences in the effects of various meteorological factors on drought in
 410 different seasons. From the results in Section 4.2, the drought propagation is affected by the combined effects of
 411 AMO, temperature, wind speed, and relative humidity in spring, with relative humidity as the main influencing
 412 factor. In summer, drought propagation is mainly influenced by AMO and temperature. In the fall, it is
 413 influenced by temperature and relative humidity, with relative humidity being the main influencing factor. In
 414 winter, it is influenced by a combination of AMO, temperature, and relative humidity, with temperature being the
 415 most important influencing factor. Comparing the four seasons, meteorological factors have the most serious
 416 effect on winter drought. In addition, there are some differences in the effects of meteorological factors on
 417 drought in different regions. Temperatures show a significant upward trend, which may mean that extreme runoff

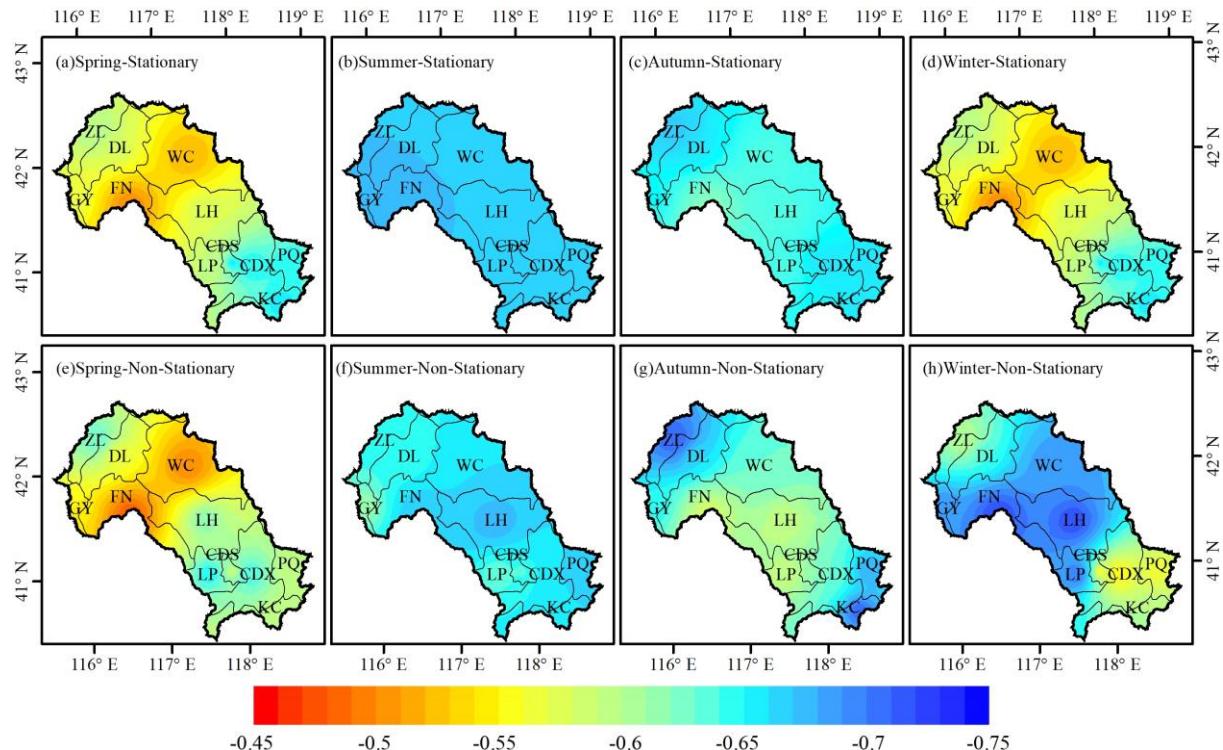

418 events will be more frequent. During the dry season, high temperatures increase evapotranspiration from surface
419 water bodies, vegetation, etc., resulting in reduced runoff and lower soil moisture content will increase the risk of
420 hydrological drought (Huang et al., 2017; Guo et al., 2021). Changes in humidity affect the efficiency of
421 evapotranspiration, and higher humidity will reduce the transfer of water from the surface and plants to the
422 atmosphere, limiting the development of drought. However, this effect may be limited by increased evaporation
423 from increasing temperatures.

424 **4.5 Drought propagation threshold**

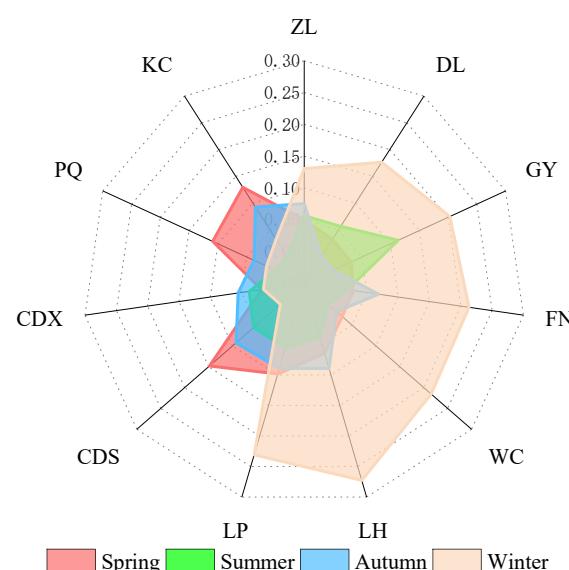

425 Based on the Copula model, the thresholds that trigger hydrological droughts under stationary and non-
426 stationary conditions (i.e., the propagation thresholds for drought) can be calculated, the results are shown in
427 Fig.11. The change rate of the meteorological drought to hydrological drought propagation thresholds are shown
428 in Fig.12. As can be seen from Fig.11 and 12, there were obvious regional and seasonal characteristics of drought
429 propagation thresholds. In this paper, the higher the drought propagation thresholds, the more likely hydrological
430 drought is to be triggered.

431 In spring (Fig.11(a)), comparing the results of calculations based on the stationary model and the non-
432 stationary model, the drought propagation thresholds were the smallest in FN, WC region, and the highest values
433 occurred in the downstream region (CDS, CDX, PQ, KC) under the stationary condition. The distribution of
434 drought propagation thresholds under non-stationary conditions was similar to that under stationary conditions.
435 In addition, compared with the stationary condition, the drought propagation thresholds were higher in most
436 regions under non-stationary condition. It indicated that hydrological droughts were more difficult to be
437 triggered in most regions under the influence of climatic factors such as temperature, specific humidity, wind
438 speed, and AMO. In summer (Fig.11(b)), There was no significant difference in drought propagation thresholds
439 in all regions under stationary conditions and non-stationary conditions. In autumn (Fig. 11(c)), the drought
440 propagation thresholds in the river basin were close to that in summer. Under stationary conditions, the drought
441 propagation thresholds were close to -0.55 in most regions. Comparing stationary conditions, the drought
442 propagation thresholds increased in ZL, PQ, and KC, while decreasing in middle-stream areas (FN, WC, LH, LP,
443 CDS, CDX) under non-stationary conditions. In winter (Fig.11(d)), there were significant differences in regional
444 drought propagation thresholds between stationary and non-stationary conditions. Under stationary conditions,
445 the drought propagation thresholds of the basin were relatively lower than those in spring, summer, and autumn,
446 with values ranging from -0.70 to -0.65. Under non-stationary conditions, the drought propagation thresholds

447 increased generally, especially in the midstream region. From Fig.12, it can be seen that drought propagation
 448 thresholds were most affected by large-scale climate factors and meteorological factors in winter, with a rate of
 449 change greater than 10% or even 20% in most regions, followed by spring, with the least change in the summer
 450 and autumn seasons. It indicated that hydrological drought was more likely to occur during winter due to climate
 451 factors.

452
 453 **Figure 11 Drought propagation thresholds in different seasons under stationary and non-stationary
 454 conditions**

455
 456 **Figure 12 The change rate of drought propagation thresholds in different seasons**

457 Comparing the four seasons, the drought propagation thresholds in most areas were relatively low in spring
458 and winter, and relatively high in summer and autumn under the stationary conditions. In contrast to winter and
459 spring, precipitation was more abundant in summer and autumn, the runoff was more sensitive to precipitation,
460 the propagation time from meteorological drought to hydrological drought was shorter, and a milder degree of
461 meteorological drought might trigger hydrological drought. However, under the influence of climatic factors, the
462 drought propagation thresholds of all four seasons changed. From the point of view of the model structure,
463 climatic factors such as AMO, specific humidity, temperature, and wind speed had an impact on the occurrence
464 of seasonal drought. Compared with spring, summer, and autumn, temperature and specific humidity had a great
465 influence on the propagation of drought in winter. The increase in temperature may be the main reason for the
466 occurrence of hydrological drought in winter.

467 **5. Discussion**

468 There are some differences in drought propagation thresholds in different regions, which may be caused by
469 the watershed characteristics, including slope and so on (Han et al., 2023, Liu et al., 2023, Zhou et al., 2021). To
470 further explore the spatial differences of propagation thresholds, the slope, average evapotranspiration, soil water
471 content (0-10 cm, 10-40 cm, 40-100 cm, 100-200 cm), and leaf area index in each region were calculated, and
472 the relationships between the propagation thresholds and the factors were explored for each region.

473 As shown in Table 10', these factors may be one of the reasons for the spatial differences in drought
474 propagation thresholds. Evapotranspiration and shallow soil moisture are dominant among these factors,
475 followed by the effects of slope and vegetation on drought propagation. Slope affects drought propagation
476 through its impact on surface runoff. When the slope increases and the water storage capacity decreases, the
477 drought resistance capacity of the basin decreases, and meteorological drought is more likely to cause
478 hydrological drought. Huang et al. (2015) pointed out that slope affects the impact of meteorological drought on
479 agricultural drought by affecting the generation of runoff in the Weihe River Basin.

480 Evapotranspiration is a key part of the water cycle and directly reflects the exchange of water between the
481 soil, vegetation, and the atmosphere. There is a positive correlation between evapotranspiration and drought
482 propagation thresholds, and an increase in evapotranspiration leads to a decrease in surface water resources,
483 which may increase the risk of drought propagation (Guo et al., 2020; Yao et al., 2022). Vegetation cover also
484 affects drought propagation, and more vegetation can increase water retention in a watershed and improve its
485 drought resistance (Zhang et al., 2022). However, when a meteorological drought is severe, vegetation in a

486 water-starved condition will consume more water through transpiration, accelerating the onset of drought. Soil
 487 moisture content may also be one of the factors causing spatial differences in drought propagation thresholds,
 488 with shallower soil having a greater impact on drought propagation than deep soil. Vegetation coverage
 489 significantly increases plant transpiration and inhibits soil evaporation to a certain extent. In general, the increase
 490 in vegetation coverage affects drought propagation by enhancing transpiration water consumption and soil
 491 moisture changes (Yang et al., 2025; Zhao et al., 2025).

492 **Table 10 The characteristics of the study area, including slope, evapotranspiration(E), soil moisture
 493 content (0-10 cm underground) (SMC0-10cm), soil moisture content (10-40 cm underground) (SMC10-

496 **6. Conclusions**

497 Many studies have pointed out that climate change and human activities significantly impact the occurrence
 498 of drought in the Luanhe River basin. In this paper, meteorological drought and hydrological drought were
 499 characterized by the SPI and SRI respectively. The drought propagation probabilities and thresholds in all
 500 seasons were calculated based on the non-stationary drought index constructed by the GAMLSS model and the
 501 Copula function, the influence of climate change and watershed characteristics on drought propagation was
 502 analyzed. The following conclusions can be drawn.

503 (1) AMO-1 and AMO-24 have a significant impact on the precipitation series in the Luanhe River basin.

504 The temperature, wind speed, and specific humidity were considered as the main influencing climate factors of
505 the runoff series.

506 (2) Based on the GAMLSS framework, both the stationary model and non-stationary model have a good
507 fitting effect on the precipitation and runoff series of the basin, but overall, the non-stationary model can capture
508 the time variation characteristics of these series more accurately.

509 (3) For most regions, the probabilities of drought propagation under non-stationary conditions were greater
510 than that under stationarity conditions. Compared to summer and autumn, spring and winter were more prone to
511 hydrological drought and may experience more severe hydrological drought.

512 (4) With regard to the drought propagation thresholds, non-stationary conditions were more likely to trigger
513 hydrological drought than stationary conditions, this phenomenon was particularly evident in the midstream and
514 upstream regions in winter, with drought propagation thresholds increasing by 0.1-0.2 under non-stationary
515 conditions compared to stationary conditions. The increase of temperature may be the key factors contributing to
516 the occurrence of hydrological drought in the basin.

517 (5) Watershed characteristics were important factors in the spatial differences of drought propagation
518 characteristics, including vegetation cover and so on. Among them, there was a high correlation (the absolute
519 value of correlation coefficient > 0.5) between evapotranspiration, soil moisture content (10-40 cm underground,
520 40-100 cm underground) and drought propagation characteristics.

521 **Limitation:** There are many driving factors for the propagation of drought, and climate change and human
522 activities are important factors among them. In this paper, we analyzed the effects of temperature, specific
523 humidity, wind speed, and large-scale climate factors on drought and its propagation. However, there are
524 numerous and complex factors that affect drought propagation, and different factors interact with each other. It is
525 necessary to consider the interaction of topography, vegetation coverage, human activities, and climate change,
526 so as to provide more effective support for drought resistance and control measures.

535 **Y Y**: Investigation, Data Curation.

536 **Acknowledgements.**

537 We are grateful to the the National Oceanic and Atmospheric Administration
538 (<http://www.esrl.noaa.gov/psd/data/climateindices>) for providing the large climate indices data, and grateful to
539 the GLDAS (https://disc.gsfc.nasa.gov/datasets/GLDAS_NOAH10_M_2.0/) for providing the average monthly
540 precipitation, temperature, wind speed, specific humidity, evapotranspiration, soil water content datasets and the
541 runoff datasets. The data and materials of the research are available.

542 **Funding Information**

543 This work was supported by the State Key Laboratory of Hydraulic Engineering Intelligent Construction and
544 Operation (No. HESS-2206), and the Open Fund of Key Laboratory of Flood & Drought Disaster Defense, the
545 Ministry of Water Resources (KYFB202307260034).
