Abstract

Digital Elevation Models (DEMs) play a key role in slope instability studies, ranging from landslide detection and recognition to landslide prediction. DEMs assist these investigations by reproducing landscape morphological features and deriving relevant predisposing factors, such as slope gradient, roughness, aspect, and curvature. Additionally, DEMs are useful for delineating map units with homogeneous morphological characteristics, such as Slope Units (SUs).

In many cases, the selection of a DEM depends on factors like accessibility and resolution, without considering its actual accuracy. In this study, we compared freely available global elevation models (ALOS, COP, FABDEM) and a national dataset (TINITALY) with a reference model (local airborne LiDAR) to identify the most suitable DEM for representing fine-scale morphology and delineating SUs in the Marche Region, Italy, for landslide susceptibility studies. Furthermore, we proposed a novel approach for selecting the optimal SUs partition.

The DEM comparison was based on several criteria, including elevation, residual DEMs, roughness indices, slope variations, and the ability to delineate SUs. TINITALY, resampled at a 30x30m pixel size, was found to be the most suitable DEM for representing fine-scale terrain morphology. It was then used to generate the optimal SUs partition among 18 combinations. These combinations were evaluated using both existing and newly integrated metrics alongside mapped landslide inventories to optimize terrain delineation and contribute to landslide susceptibility studies.

Introduction

Open-access global DEMs have been commonly used for a vast range of geomorphological studies, which have required modelling or analysis of terrain surface in mountain environments, where these DEMs have been characterized by a marked quality deterioration (Guth et al., 2024; Trevisani et al., 2023b). One of the many uses of DEMs has been to serve as the base input for analyzing landslides morphological features, state and style of activity and generating landslide susceptibility models (Brock et al., 2020). Among multiple methods of data-driven (Ahmed et al., 2023; Lombardo et al., 2020; Lombardo and Tanyas, 2020; Titti et al., 2021a) and physical-

based models (Van den Bout et al., 2021) to predict, investigate (Brenning, 2005; Pirasteh and Li, 2017; Steger et al., 2023) and detect landslides (Qin et al., 2013), the elevation model has been of essential use. DEMs are utilized to derive terrain-based characteristics (Brock et al., 2020; Mahalingam and Olsen, 2016) which have been conditioned by their resolution. In the literature, DEM resolution and its influence have been tested in several aspects such as: in landslide modelling and hazard assessment (Catani et al., 2013; Claessens et al., 2005; Fenton et al., 2013; Huang et al., 2023), in 3D physical models (Qiu et al., 2022), as well as morphological quality assessment explored at regional scales (Grohmann, 2018; Hawker et al., 2019; Trevisani et al., 2023b).

Comparisons among DEMs to evaluate the most suitable product are based on different criteria and the results have likely varied as per the test site. Thus, even if the same criteria have been used to rank DEMs, regional topography has influenced the preference of the elevation model in different areas (Florinsky et al., 2019; Zhang et al., 2019). Landcover has been specifically important when global DEMs (Bielski et al., 2024), such as Copernicus GLO-30 (COP) and Advanced Land Observing Satellite (ALOS) World 3D-30m, have been used for deriving a Digital Terrain Model (DTM), given that most of the times these products resembled more a Digital Surface Model (DSM: Guth & Geoffroy, 2021).

An ongoing initiative, the Digital Elevation Model Inter-comparison eXercise (DEMIX; Strobl et al., 2021), has aimed to align methodologies allowing for criteria-based ranking of global DEMs. In the first application (Bielski et al 2024), metrics related to slope and roughness have been considered in addition to those related to elevation differences; the approach has further developed, adopting new metrics and a wide range of geomorphometric derivatives (Guth et al., 2024). Global DEMs have been commonly used in geoscientific research due to their spatial extent and public accessibility whereas national DEMs (Gesch et al., 2018; Muralikrishnan et al., 2013; Tarquini et al., 2007) have generally been tailored to represent country-specific land surface and morphology at a higher spatial resolution and accuracy to serve geoscience applications. Shuttle Radar Topography Mission (SRTM; Jarvis et al., 2008), ALOS (Takaku et al., 2014), Terra Advanced Spaceborne Thermal Emission and Reflection Radiometer Global DEM (ASTER GDEM; Abrams et al., 2010) have been among the most widely used, freely accessible and initial global DEMs utilized in geomorphic analysis (Becek, 2014; Florinsky et al., 2019; Mahalingam and Olsen, 2016; Trevisani et al., 2023b; Zhang et al., 2019). However, several factors must be considered when implementing these global datasets in a localized area for landslide recognition, mapping, and assessment.

Landslide inventories and elevation models have been essential inputs for data-driven landslide models, for which the DEM has been used to derive morphological parameters such as slope angle and slope aspect. For these derivatives to be as accurate as possible in a model, the DEM quality (Claessens et al., 2005; Mahalingam and Olsen, 2016; Saleem et al., 2019) should satisfy the representation of fine-scale morphology (Chaplot et al., 2006; Florinsky, 1998). In other words, the DEM quality has significantly affected the prediction capacity of a model. The errors contained within a DEM, even when small, propagate in derivatives of elevation (Karakas et al., 2022; Mahalingam and Olsen, 2016; Pawluszek and Borkowski, 2017; Saleem et al., 2019) which have been weighed as important factors in landslide occurrence. The various available DEMs have been generated using a range of technologies. While significant efforts have been made to improve DEMs over time, the accuracy of these models has remained a critical issue. Selecting an appropriate DEM has proven to be more important than the number of DEM-derived factors used in landslide assessment (Kamiński, 2020).

74 Another use of DEMs has been the delineation of mapping units (Schlögel et al., 2018). Mapping units have been

75 used to subdivide the study area in homogeneous, elemental units such as: administrative units (Lombardo et al.,

76 2019), terrain units (Van Westen et al., 1997), unique condition units (Titti et al., 2021b), grid cells (Reichenbach

77 et al., 2018) or SUs (Ahmed et al., 2023). SUs were initially introduced by Carrara et al. (1991) as portions of

78 territory, presenting homogeneous morphological characteristics for landslide identification and susceptibility

79 mapping. The SU, according to the scale adopted, has served as a solution that adequately represents unstable

80 slopes.

81 To assess the suitability of DEMs for landslide susceptibility and prediction, it has been essential to conduct a

82 quality assessment of these models which has commonly referred to the spatial resolution alone. Therefore, global

83 DSMs and a national Italian DTM has been compared with a local accurate elevation model (Airborne LiDAR)

84 in the context of terrain representation and its delineation. The Italian DTM has been already investigated in some

85 studies, mainly focusing on hydrogeomorphology studies (Pulighe and Fava, 2013; Zingaro et al., 2021; Annis et

86 al., 2020; Tavares da Costa et al., 2019). Accordingly, the quality evaluation from the perspective of fine-scale

87 morphology and geomorphometric derivatives in the context of landslide science has remained an interesting

88 aspect to elaborate on.

89 This study has aimed to optimize inputs used for representing morphological data in landslide susceptibility

90 assessment and to understand their interactions by: identifying the most suitable DEM for accurately representing

91 fine-scale slope morphology; proposing a new metric for analyzing optimal SU parameters for landslide

92 susceptibility mapping, integrating landslide inventory data with landslide area and numerosity; extending and

93 applying the methodology to test landslide susceptibility at a regional scale in the Marche Region of Central Italy.

94 **Study Area**

95 In this study, we have selected two distinct study areas. The first Area of Interest (AOIa) has encompassed the

96 entire Marche region, located in central-eastern Italy (Figure 1, AOIa). From the morphological point of view, this

97 region is characterized by three different types of landforms that extend in the north-south direction. In the western

98 part, the region has been crossed by the Apennines which can reach, in the area, a peak of 2476m a.s.l. at Monte

99 Vettore. Then, the reliefs degrade to more rounded hills in the central part of the region till the flat eastern coastal

100 strip. From a geological perspective, the Apennines, a Neogene fold-and-thrust belt that formed following the

101 closure of the Mesozoic Tethys Ocean, is characterized by calcareous units, calcareous-marly and arenaceous

102 units, as well as pelitic-arenaceous and marly-arenaceous units, ranging in age from the Jurassic to the Neogene.

103 have mainly been characterized by Neocene/quaternary clayey formations. Several small rivers traverse the region

104 from the west to the east side. In particular, the basins of Misa, Esino, Cesano, and Metauro rivers were affected

105 by an exceptional thunderstorm in September 2022 which triggered floods and landslides (Corti et al., 2024). One

106 of the highest rainfall intensity of the 2022 event was registered in a sub-portion of the Marche region, that has

107 been selected as the second study area (AOIb) for this work (Figure 1, AOIb). This selection is based not only on

108 the consequences of the exceptional rainfall event but also on the fact that, morphologically, it represents a typical

109 sample of the Marche mountainous region. has been covered by a high-resolution dataset (1m pixel size) which

110 allows us to effectively conduct the experiments as described in the following text.

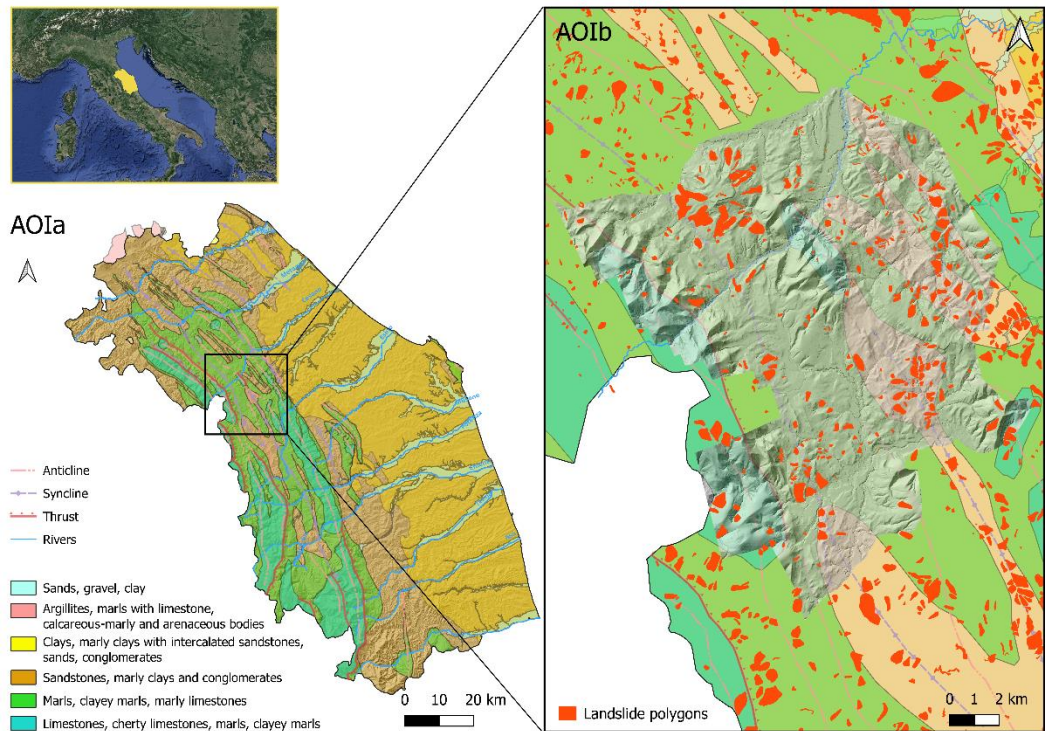
A relevant portion of the territory of Marche region (AOIa) presents slope failures. The most populated dataset of landslide in the area is the inventory of the Piano stralcio per l'Assetto Idrogeologico (PAI) of Marche Region (Figure 1). In the area of Marche region (AOIa), the PAI counts 19,296 inventoried landslides for a total landslide area of 1394 km^2 which covers 15% of the total regional surface classified as flow, slide and complex landslides (Cruden and Varnes, 1996).


Figure 1: **Study area in central Italy. On the left, is the study area AOIa, encompassing the entire Marche region which has been analyzed in the second phase of the study. The geological classification is ordered by age (Quaternary, Cretaceous-Lower Pliocene, Lower Pliocene-Lower Pleistocene, Middle-Upper Miocene, Upper Eocene-Upper Miocene, Upper Trias-Middle Eocene) . On the right is study area AOIb, a sub-portion of the Marche region where we conducted the DEM analysis in the first phase covered by the 1m pixel size airborne LiDAR survey. The Piano Stralcio per l'Assetto Idrogeologico (PAI) landslide inventory of the Marche Region identifies 19,296 landslide bodies as polygons.**

Materials and Methods

The methodology implemented in this study has aimed to assess the quality of freely available DEMs, framing their use for landslide susceptibility assessment. DEMs have been essential because they allow the derivation of landslide predisposing factors and generate a morphology-based terrain subdivision: SUs. Thus, these two uses of a DEM in landslide susceptibility assessment have been investigated.

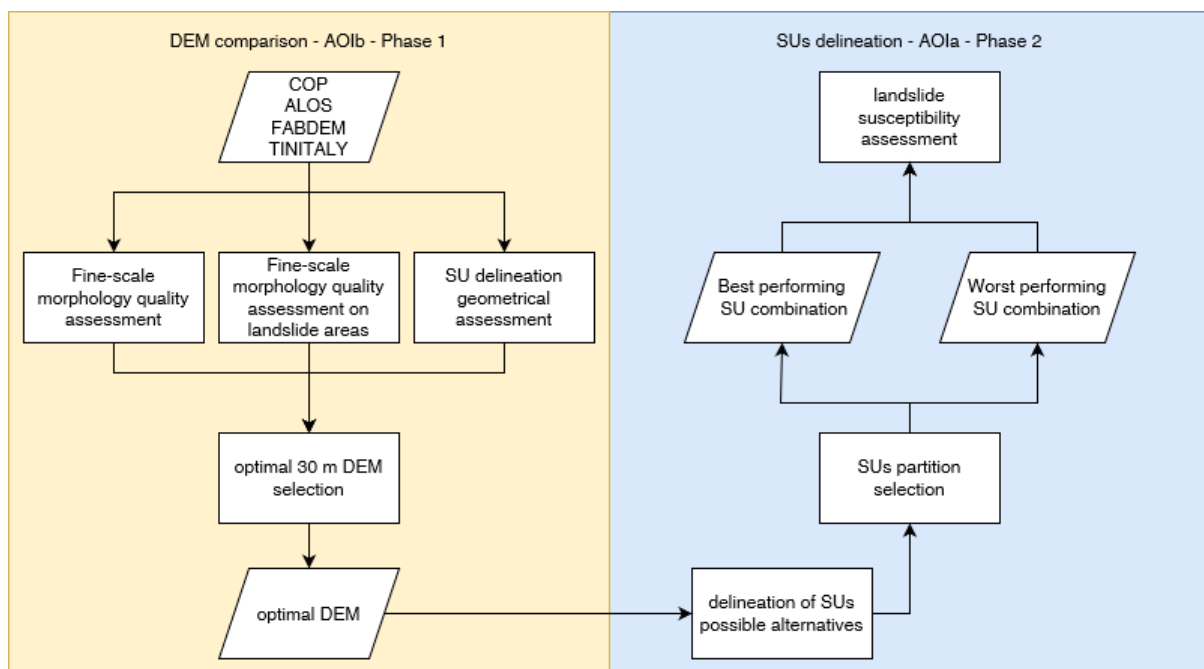
The analysis has been conducted in two sequential phases (Figure 2): in the first phase the differences in DEM derivatives have been assessed by comparing global and a national DEM to a local high-resolution reference elevation data in AOIb. In the second phase we have evaluated 18 SU partitions on the base of internal/external homogeneity, landslide extension and landslide number using the best performing open-source DEM, which has been identified in the first phase of this study.


Figure 2: Workflow of the two-phases analysis. Phase 1 DEM assessment: comparison of global and national DEM to a local high-resolution reference elevation model (with reference to AOIb). Phase 2 Slope Units delineation: selection of the optimal parameters for SUs delineation (with reference to AOIa).

Phase 1: DEM assessment

In this phase, the accuracy of three global DEMs, as mentioned below, and one national DEM (TINITALY) has been evaluated by a comparison with a local airborne LiDAR in the study area AOIb.

ALOS (ALOS World 3D - 30m. V3.2, 2024) has been released by Japan Aerospace Exploration Agency (JAXA) in 2015, at a horizontal resolution of 1 arc-second, approximately 30 meters as a DSM (Caglar et al., 2018). This product, surveyed from 2006 to 2011, uses the 5-meter mesh of "World 3D Topographic Data" and is provided in two resampled versions by JAXA (mean resampling kernel is used in this study), with elevation expressed according to the Earth Gravitational Model 1996 (EGM96).

COP (European Space Agency, 2024), has been obtained from the WorldDEM at 1 arc second as a DSM, a product of the radar data acquisition of 12 meters TanDEM-X mission from 2011 to 2015. Forest And Buildings removed COP DEM (FABDEM; Hawker et al., 2022), has been made available as a corrected global DTM available at 1 arc-second grid spacing (60°S-80°N) derived from COP. Machine learning techniques have been devised to improve mean absolute vertical error in built-up and forested areas in comparison to COP (Hawker et al., 2022). Both FABDEM and COP elevations have been referred to EGM 2008 geoid.

TINITALY's 1.0 (Tarquini et al., 2007), and version 1.1 (Tarquini et al., 2023), has covered the whole of Italian territory, as a DTM available at 10m pixel size. Heterogenous data, mainly based on Technical Regional Cartography (CTR) with elevations derived by means of photogrammetric method, has been used to build a national scale model. In particular, the CTR map scaled at 1:10000 with 10m interval for contour lines is used for Marche region in the compilation of TINITALY. A Triangular Irregular Network (TIN) structure has been employed in constructing the DEM to tackle varying data density and redundancy. Merging various types of input data is followed by significant investigation to ensure the seamless production of a high resolution and considerably the most accurate representation for Italy, with a root mean square error ranging from 0.1 to 6 meters (Tarquini et al., 2007).

The reference DEM (as called hereafter) has been a DTM acquired in 2012 using airborne LiDAR, with a pixel size of 1x1m, and a reported vertical and planimetric accuracy of 15 cm and 30 cm, respectively (Ministero dell'Ambiente e della Sicurezza Energetica, https://gn.mase.gov.it/portale/pst-dati-lidar). This reference DTM has been aggregated via averaging the pixel size to 30m.

The global DEMs (COP, FABDEM, ALOS) and TINITALY have been projected in WGS84 UTM 33N with a pixel size of 30 and 10 meters respectively using bilinear interpolation for alignment with the reference DEM. The inclusion of COP and FABDEM, along with ALOS as a global DEM and TINITALY as a national-scale elevation model for comparison, has been invoked by several studies (Bielski et al., 2024; Guth & Geoffroy, 2021; Meadows et al., 2024; Osama et al., 2023; Trevisani et al., 2023). All the DEMs, except TINITALY (geoid model not publicly available), have been transformed to a common geoid model, EGM2008 respectively for alignment and comparison with the reference grid. TINITALY is based on the Italian geodetic network (IGM95) where the measured ground points have been described by the Italian geoid called ITALGEO 2005 (Albertella et al., 2008; Barzaghi et al., 2007). Barzaghi and Carrion (2009) have concluded that the difference between ITALGEO05 (regional geoid model) and EGM2008 (global geoid model) is negligible for many applications, and both are capable to represent the region of Italy. Therefore, no geoid transformation for TINITALY has been required.

To perform the quality assessment of selected DEMs, elevation differences have been considered for compatibility with precedent studies. Indeed, studies focusing on DEMs comparison (Polidori and Hage, 2020) are generally based on elevation differences, using standard statistical metrics such as standard deviation and Root Mean Square Error (RMSE), and in some cases slope and aspect have been considered (Meadows et al., 2024; Zhang et al., 2019). However, as suggested in many studies (Bielski et al., 2024; Crema et al., 2020; Florinsky et al., 2019; Gesch, 2018; Guth & Geoffroy, 2021; Kakavas et al., 2020; Liu et al., 2019; Purinton & Bookhagen, 2017; Trevisani et al., 2023), statistical metrics of elevation differences alone fail to fully capture the quality of DEMs, including the capability to represent fine-scale morphology and the presence of artifacts. Therefore, for this reason

185 and because the focus of the work has been to investigate mainly the accuracy of the DEMs geomorphometric
186 derivatives, along with the differences in elevation, a straightforward and simple approach to take the local spatial
187 variability of surfaces into account based on a geostatistical-based methodology (Isaaks and Srivastava, 1989), as
188 discussed by Trevisani et al. (2023b), has been proposed.

189 The approach has been based on the derivation of a residual DEM, also known as Topographic Position Index
190 (TPI; Guisan et al., 1999; Hiller and Smith, 2008; Wilson and Gallant, 2000), and the calculation of roughness
191 indices. The residual DEM, derived by detrending the original surface, has permitted to highlight the capability
192 of DEMs to reproduce local fine-scale morphology. Moreover, the residual DEM has been used as input for the
193 calculation of roughness indices such as the standard deviation of residual DEM (Grohmann et al., 2011) or even
194 geostatistical based estimators such as the variogram (Eq 1, with p = 2), the madogram (Eq. 1, with p = 1) and
195 (Eq. 2) represents the more robust Median Absolute Differences (MAD; Trevisani and Cavalli, 2016; Trevisani
196 and Rocca, 2015). The generalization of the variogram have been described as in Eq. (1) and MAD as Eq. (2);

197 $$\gamma(\boldsymbol{h})_p = \frac{1}{2N(\boldsymbol{h})} \sum_{\alpha=1}^{N(\boldsymbol{h})} |z(\boldsymbol{u}_a) - z(\boldsymbol{u}_a + \boldsymbol{h})|^p = \frac{1}{2} \cdot mean(|\Delta(\boldsymbol{h})|^p), \qquad (1)$$

198 where,

199 $$\Delta(\boldsymbol{h})_a = z(\boldsymbol{u}_a) - z(\boldsymbol{u}_a + \boldsymbol{h})$$

200 $$\mathrm{MAD}(\boldsymbol{h}) = |\Delta(\boldsymbol{h})_{\alpha=median}|, \quad (2)$$

201 where $\boldsymbol{h}$ is the separation vector (lag) between two locations (u), $z(u)$ is the value of the variable of interest in
202 the location u (e.g., residual elevation), and N($\boldsymbol{h}$) is the number of point pairs with a separation vector $\boldsymbol{h}$ found in
203 the search window considered. Accordingly, the variogram is the half of the mean squared differences $\Delta(h)_a$ and
204 the MAD is the median of the absolute differences $\Delta(h)_a$. It should be highlighted that there are roughness indices
205 such as MAD$_{k2}$ and the Radial Roughness Index (RRI) that have been calculated directly from the DEM, without
206 detrending (Trevisani et al., 2023c, a).

207 A simple short-range omnidirectional roughness index, such as MAD calculated for lag distances of 2 pixels and
208 circular kernel of 3 pixels, permits to analyze fine-grain roughness (see Trevisani et al., 2023a; Trevisani and
209 Rocca, 2015 for a full discussion). The MAD omnidirectional roughness index essentially provides a measure of
210 omnidirectional spatial variability (median differences in residual elevation) by comparing all pixel values
211 separated by a distance of |h| pixels in the moving window considered. An alternative roughness index which does
212 not require the definition of calculation parameters is the RRI (Trevisani et al., 2023c), that has been derived to
213 improve the popular Topographic Ruggedness Index (TRI; Riley et al., 1999).

214 All the comparisons have been done using a pixel size of 30x30m. This value was assumed because it is closer to
215 the size of global 1 arc second DEMs, except for TINITALY which is released with a pixel size of 10x10m.
216 TINITALY has been upscaled by mean-pixel aggregation to 30x30m pixel size. The 30m DEM (TINITALY30m)
217 has also been compared with the 10m pixel size version (TINITALY10m) in AOIb to assess the effect of upscaling
218 on the analysis. The aggregation at 30m permits to filter out or at least reduce some characteristics artifacts of
219 TINITALY, such as triangular patterns, due to interpolation in areas of low data density, and artificial terraces, due
220 to the interpolation of contour lines. Given that, slope, roughness indices and residual DEM are scale-dependent

geomorphometric derivatives, a normalization has been done to compare the results of the differences between the derivatives at different resolutions of TINITALY and the reference DEM. Accordigly, a normalized difference has been adopted for each derivative D:

$$(D_{TINITALY} - D_{reference\ DEM}) / (D_{TINITALY} + D_{reference\ DEM}).$$

Finally, an additional analysis has been conducted. Since the goal of the research proposes attribution to landslide studies, the DEM-derived slope difference distribution in the landslide areas delineated by the PAI inventory is also included. To prevent overestimation of landslide areas, polygons contained within or significantly overlapping another polygon (primarily representing landslide reactivations) have been merged.

To further assist in evaluating the quality of DEMs in the frame of landslide susceptibility assessment, the SUs have been generated using various DEMs (global and national). This has allowed for a comparison of the SUs produced from the reference DEM with those derived from the global DEMs under evaluation, highlighting any differences in terrain partitioning and geometry. The software r.slopeunits (Alvioli et al., 2016) has been used to generate the SU maps, starting from the SU parameters proposed by Alvioli et al. (2016) for AOIb. After a few corrections and optimizations, the parameters have been set as: flow accumulation threshold to 5×10^5 m^2, minimum SU area as 80,000 m^2, circular variance as 0.4 and clean size of 60,000 m^2 with the cleaning method (flag -m) that removes SU smaller than the clean size as well as removes odd-shaped polygons and SUs with width as small as two grid cells (Alvioli et al., 2016). To quantify the similarity between SUs derived from reference DEM and from each DEM under observation, the Jaccard Index (Jaccard, 1901) has been utilized to estimate Intersection-over-Union (IoU) ratio between the reference (in this case SU derived from reference DEM) and the predicted (in this case the DEM under test). The Jaccard Index can measure the segmentation of the SU in reference to the overlapping of the defined shape and similarity of terrain-representation. Ranging from 0, signifying no similarity, to 1 that signifies identical sets, this index considers the combined size which is inclusive of the intersection. Hence, the higher the index value, the better delineation of terrain as per the considered reference.

Phase 2: Slope Units delineation

This phase of the work has been focused on the identification of the most representative and freely available DEM to subdivide the study area in SUs for landslide modelling. Therefore, 18 SUs partitions have been generated with r.slopeunits software and then compared with landslide areas and landslide counts mapped in the AOIa to find the optimal ones. The optimal DEM obtained from the first phase has been used to test SU delineation in the study area with a range of parameters. As proposed by Alvioli et al. (2016), an aspect segmentation metric has been used to analyze the optimal parameters for the Marche region, altering two parameters: the minimum surface area of SU and the minimum circular variance for terrain, and fixing the parameters flow accumulation and clean size.

The aspect segmentation metric has been based on the concept of partitioning terrain by grouping pixels sharing similar aspect properties. This has been transferred to SU delineation, with the assumption, given the partitioning has been evaluated by the internal homogeneity and external heterogeneity of SU. The aspect segmentation metric can be written as:

257 $\quad F(a,c) = \frac{V_{max} - V}{V_{max} - V_{min}} + \frac{I_{max} - I}{I_{max} - I_{min}}$,   (3)

258 where V (SU homogeneity) is the local aspect variance and I is the autocorrelation which represents the external

259 heterogeneity of the adjacent SUs and F evaluates the morphometric delineation of the SUs, explained by the

260 minimum surface area of a SU (a) and the minimum circular variance (c) (see for more details, Alvioli et al.,

261 2016). The first term of F value is estimated based on the homogeneity of pixels grouped in a single SU, thus a

262 higher value represents a better segmentation. In the same way, on the base of the second term of Eq. 3, the greater

263 the difference between the average aspect value of each SU and each of the relative adjacent SU, the higher is the

264 F value. Overall, from a geometrical point of view the optimal a and c combination is the one that maximizes the

265 metric value.

266 Differently from Alvioli et al. (2016) where the Area Under the Curve (AUC) derived from landslide susceptibility

267 assessment has been also considered in selecting the optimal SU parameters, this study proposes to compare the

268 landslides extension (A) and landslide density (D) per SU. The former sums the percentage of the landslide area

269 included inside the SU where the failure has been triggered (from the initiation point). The latter is the inverse of

270 the average number of landslides in each SU. A and D can be expressed as;

271 $\quad A = \frac{\sum_{i=1}^{N} l_i}{L_i}$,   (4)

272 $\quad \frac{1}{D} = \frac{\sum_{i=1}^{N} d_i}{N}$,   (5)

273 where L_i , in Eq. 4, is the total landslide area of all the events triggered in the ith SU, l_i is the cumulative landslides

274 area inside the ith SU which excludes the extension of landslide that occupies adjacent SUs, N, in Eq. 5, is the

275 number of unstable SUs, d_i is the number of landslides triggered in the ith SU.

276 $\quad S(a,c) = \frac{F(a,c) - F_{min}(a,c)}{F_{max}(a,c) - F_{min}(a,c)} \cdot \frac{A(a,c) - A_{min}(a,c)}{A_{max}(a,c) - A_{min}(a,c)} \cdot \frac{D(a,c) - D_{min}(a,c)}{D_{max}(a,c) - D_{min}(a,c)}$,   (6)

277 where S is the final metric which combines F, A and D. The optimal combination of a and c for SU delineation in

278 the study area selected is the one that maximizes the S metric in Eq. 6. SU parameters for the experiment on entire

279 Marche region have been tested with; flow accumulation threshold to 10×10^5 m^2, clean size of 20,000 m^2 with the

280 cleaning method (flag -m). Minimum area (a) has been tested with 40, 80, 150, 200, 300 and 500x10^3 m^2 with

281 corresponding circular variance (c) of 0.1, 0.4 and 0.7 for each a, making 18 combinations.

282 The Susceptibility Zoning plugin (SZ-plugin), integrated with QGIS and developed by Titti et al. (2022), has been

283 used to calculate the aspect segmentation metric (F) and to map the landslide susceptibility in the Marche region

284 (AOIa). This analysis has utilized the DEM selected in Phase 1 and assessed four SU delineations, ranked from

285 highest to lowest performance, as mapping units for evaluating landslide susceptibility. The analysis has been

286 conducted using a Generalized Additive Model (Loche et al., 2023). The covariates selection includes: lithology,

287 from national dataset (http://portalesgi.isprambiente.it/), landcover (2018 CORINE, https://land.copernicus.eu/en)

288 as categorical covariates. The continuous covariates have been generated using the Spatial Reduction Tool (Titti

289 et al., 2022) from the phase 1-selected DEM as derivatives; slope angle, planar and profile curvature as ordinal

290 covariates and northness, eastness as linear covariates. The collinearity between the predisposing factors has been

291 evaluated by the Pearson's coefficient. The results have been validated with a 10-fold spatial cross-validation
292 which clusters the dataset with a k-means approach (Elia et al., 2023). The overall prediction capacity has been
293 estimated with ROC-based AUC (Fawcett, 2006), F1 score (Singhal, 2001) and Coen's Kappa score (K; Kraemer,
294 2015).

295 **Results**

296 The differences between elevation, residual DEMs, roughness indices and slope variations within the four selected
297 open-access DEMs and the reference DEM have been shown in Figure 3. The boxplots report the distribution of
298 the differences higlighting the median, the first and the third quartile excluding the outlayers. Moreover, since the
299 differences report positive and negative values, the absolute mean difference has been calculated. Therefore, the
300 lower the variance and the absolute mean difference, the better is the output considered.

301 Overall, TINITALY resampled at 30m (TINITALY30m) has showcased the best performance across all metrics,
302 with a smaller distribution of differences and lower absolute mean difference. ALOS, on the other hand, has
303 displayed the largest difference among all DEMs across all metrics. Between COP and FABDEM, COP has shown
304 a larger distribution of elevation differences, and as expected, COP has had a stronger tendency to overestimate
305 elevation with respect to FABDEM (Figure 3). However, for slope (Figure 3B) and isotropic roughness (Figure
306 3C), FABDEM has displayed more spread in differences.

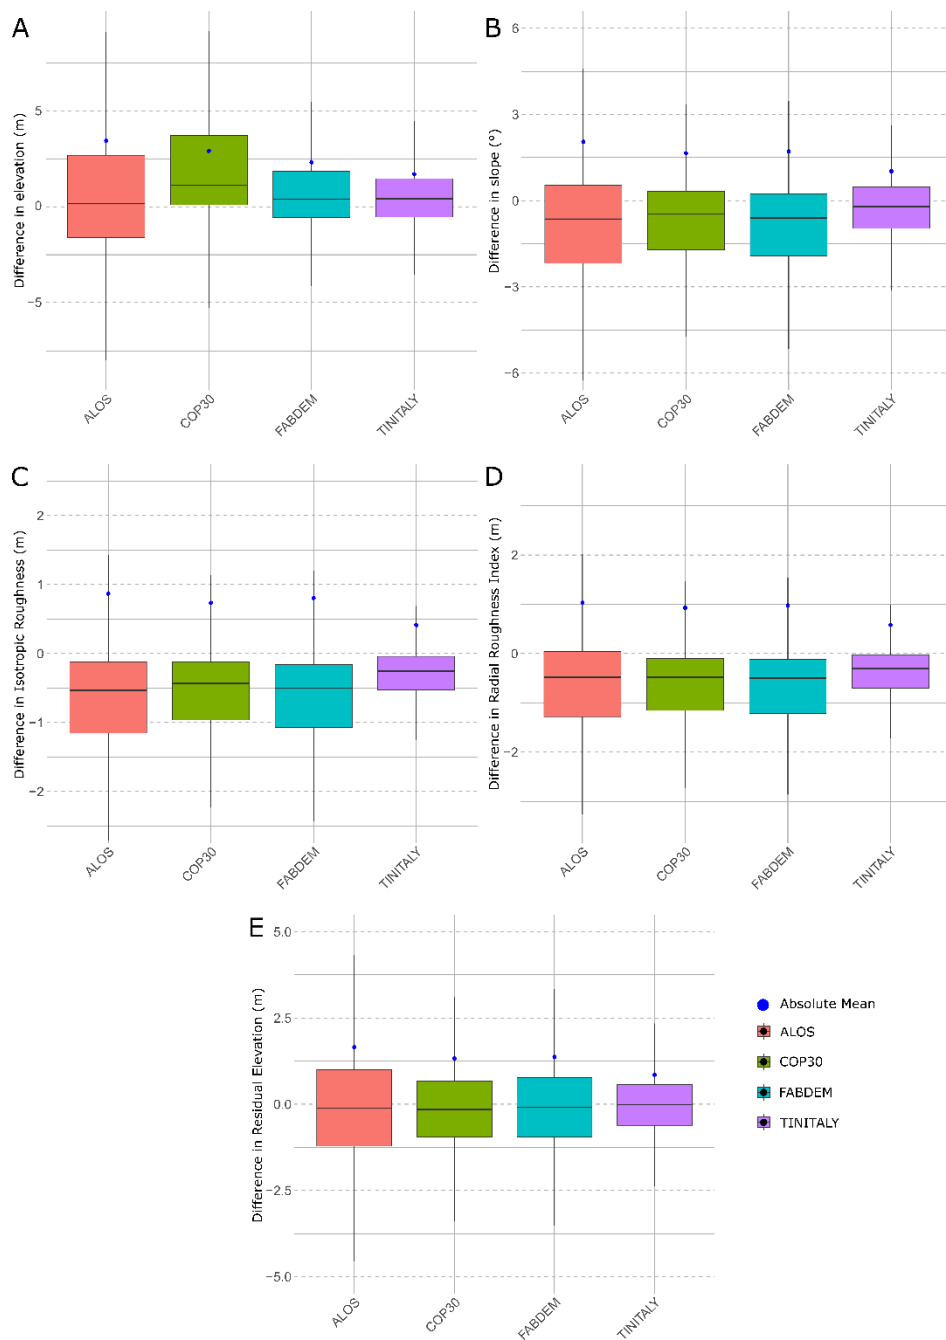
307


Figure 3:Boxplots visualizing the differences among the DEMs at 30 meters, using different metrics with the absolute mean calculated; A) Elevation, B) Slope, C) Isotropic Roughness Index, D) Radial Roughness Index and E) Residual DEM.

311 Figure 4 exhibits the differences of the selected derivatives between TINITALY30m and TINITALY10m. Apart
312 the elevation, TINITALY at 10m is quantifying a larger distributions in normalized differences for the terrain
313 indices. The absolute mean difference confirms the trend.

314
Figure 4: Boxplots showing the differences in TINITALY at 10m and 30m with respect to the reference LiDAR at the respective resolution, for different indices with the absolute mean calculated; A) Elevation, B) Slope, C) Isotropic Roughness Index, D) Radial Roughness Index and E) Residual DEM.

318   Since the main topic of our analysis is to support landslide susceptibility mapping, we have investigated the
319   performance of the selected DEMs to derive slope, which is considered one of the most relevant landslide
320   predisposing factors, in the area where landslide bodies have been mapped. Figure 5 shows the slope-difference
321   within the mapped polygons of the PAI landslide inventory. TINITALY30m is seen to have the smallest differences
322   in terms of absolute mean and the distribution among all the other DEMs (Figure 5A). Similarly, in Figure 5B,
323   the distributions of the normalized differences of TINITALY 10m and 30m clearly highlight the larger differences
324   distribution of the 10m DEM.
Figure 5: A) Slope differences for 30m DEMs as compared to the reference DEM in PAI landslide polygons. B) Normalized difference in slope with reference DEM for 10m and 30m TINITALY in PAI landslide polygons.

The last part of the DEMs comparison would investigate the effect on the SUs delineation of different DEMs. Table 1 reports the Jaccard index tested comparing the SUs delineated with DEMs at 30m and SU generated with the reference DEM. The highest similarity index is for TINITALY30m.

Table 1: Jaccard Index represented as Intersection-over-union for SUs generated from the DEMs under test with the reference LiDAR DEM SUs.

DEM	IoU
ALOS	0.866
FABDEM	0.896
COP	0.887
TINITALY30m	0.912

The second phase of the analysis has been focused on the optimal SUs delineation to assess landslide susceptibility in AOIa. Since in the previous analysis TINITALY30m has been found as the most accurate DEM to represent the morphology of the mountainous area of the Marche region, we have generated 18 SU combinations based on TINITALY30m to find the optimal SUs partition of AOIa. Figure 6 shows the visual differences in delineation for some of the parameter combinations. Smaller values of circular variance and minimum area result in smaller dimensions of SUs which can restrict heterogeneity between adjacent SUs while, ideally, SUs should maintain external heterogeneity for better terrain representation.
Figure 6: SU combinations. 9 out of the 18 combinations are shown to highlight differences as the values of two parameters change, i.e., minimum area and circular variance.

Figure 7 reports the behavior of the *F, A* and *D* metrics and the final S metric based on the 18 combinations of *a* and *c*. Considering that each of the metric represents a goodness for the final SU partition, higher the *F, A* and *D*, better is the SU partition. Excluding *F,* which shows an almost irregular pattern with the maximum at *c* equal to 0.1 and *a* equal to $40 \times 10^3 m^2$ (Figure 7.1). *A* and *D* have a mutually opposite almost linear pattern which reach a maximum pairing: in A where *c* is equal to 0.7 and *a* is each of the values assigned (Figure 7.2), in *D* with *c* equal to 0.1 and *a* equal to $40 \times 10^3 m^2$ (Figure 7.3). *A* shows a better performance increasing the mapping unit extension of the study area, whereas *D* shows better performance with smaller partitions.

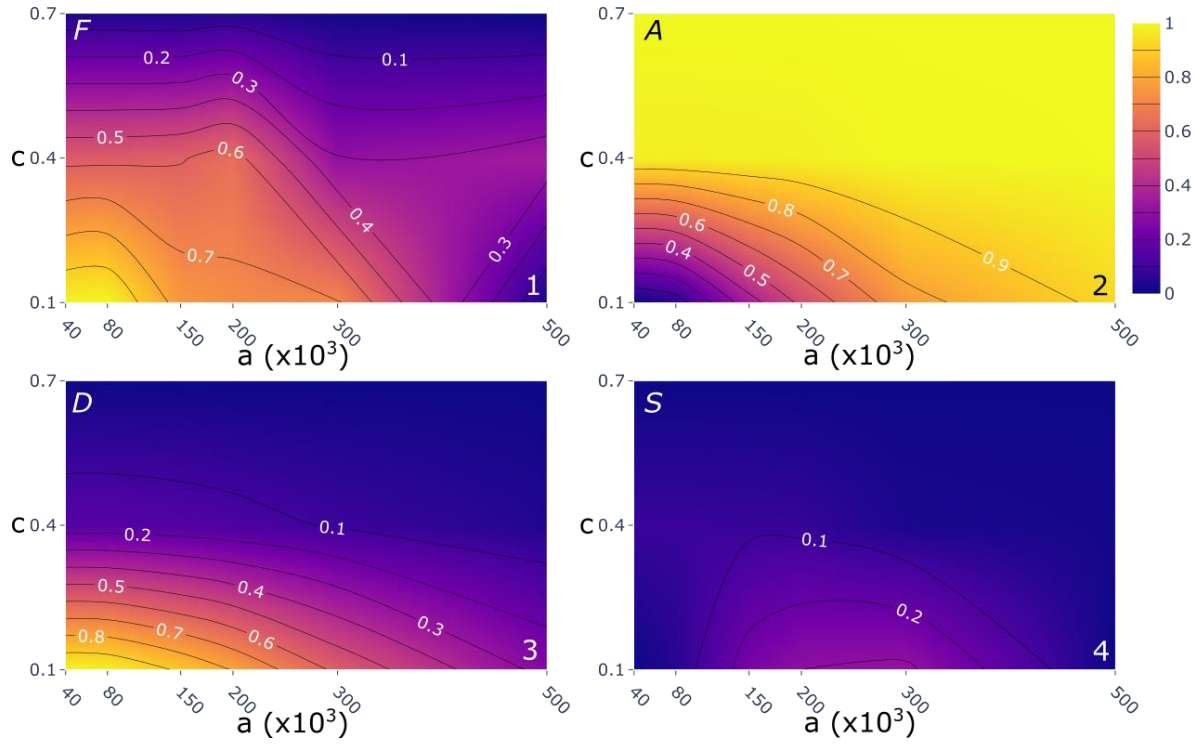
The product of the normalized metrics results in the *S* value which is maximized in the range of *a* between 300×10^3 m^2 and 200×10^3 m^2 and by a value of 0.1 for *c* (Figure 7.4). Therefore, among the tested combinations, *c* equal to 0.1 and *a* equal to 300×10^3 m^2 produce the optimal SU partition for landslide susceptibility mapping in the Marche region with a SU extension of 0.40 km^2 on average (dataset freely available on Ahmed and Titti, 2024). On the contrary the worst-case partition is the one which combines *c* equal to 150×10^3 m^2 and *a* equal to 0.7 with a SU extension of 0.84 km^2 on average.


Figure 7: Behavior of the *F, A* and *D* metrics and the final S metric with respect to parameters *a* and *c*: (1) shows the F value of SU aspect segmentation metric, (2) visualizes the landslide extension inside a SU (*A*), (3) shows the landslide density (*D*) and (4) depicts the results of the final combined metric *S*.

Consequently, the susceptibility assessment with the S-optimal and S-worst case SUs partition has been carried out. The maps resulting from the susceptibility analysis and the relative confusion matrixes based on the S-optimal and the S-worst case SUs delineation of TINITALY30m dataset are represented in Figure 8, while the quality metrics generated from the 10-fold spatial cross validation by ROC analysis are reported in Figure 9. The summary of these metrics is provided in Table 2.

Table 2: Summary of confusion matrix from maps in Figure 8 and performance metrics in Figure 9.

	True Positive (TP)	True Negative (TN)	False Positive (FP)	False Negative (FN)	AUC	F1 score	Cohen's Kappa Index
S-optimal	37%	6%	31%	26%	0.68	0.6	0.23
S-worst case	45%	6%	24%	25%	0.74	0.67	0.29

In addition, two more landslide susceptibility analysis have been carried out using SUs partitions with intermediate S values: *c* equal to 200×10^3 m² and *a* equal to 0.4, *c* equal to 40×10^3 m² and *a* equal to 0.1, to investigate the relation between AUC and the number, or extension, of the slope units (see Discussion section).

Discussion

Based on the results of the quantitative comparison between ALOS, COP, FABDEM, TINITALY10m and TINITALY30m, the latter has performed better than the other DEMs as per the indices used in this study (Figure 3). These comparisons are insightful for morphological differences for instance, in regard to roughness indices (Figure 3D), all DEMs tend to oversmooth with respect to the reference DEM. This can be indicative of the spatial support being larger than 30m in reality, meaning that the spatial data density is much lower than the given resolution. It is also interesting to realize the difference between COP and FABDEM. FABDEM (DTM) being a product of COP (DSM), in essence should be closer to the LiDAR representation of the terrain with vegetation and buildings removed, but it produces a less accurate output. The efforts of generating a DTM from COP have been motivated in the application of flood modelling trying to optimize the terrain representation, especially in areas of relatively low elevation. However, the algorithm has not been devised for optimizing geomorphometric derivatives such as slope (Hawker et al., 2022). This can be particularly relevant when modelling slope instability. Thus, FABDEM in the region considered does not improve the terrain representation as compared to COP (Bielski et al., 2024). This behavior is visible in Figure 3 where FABDEM shows larger difference distributions than COP for slope, residual DEM and both roughness indices. For instance, in regard to roughness indices (Figure 3D), all DEMs tend to oversmooth with respect to the reference DEM which can be indicative of the spatial support being larger than 30m in reality, meaning that the spatial data density is much lower than the given resolution.

ALOS consistently features high differences in all computed metrics against the counter global DEMs which could be explained with the analysis of Caglar et al. (2018). They concluded that ALOS contains a significant number of anomalies in elevation values, possibly attributed to unfiltered sensor noise and processing algorithms which are often not easily identifiable. Nonetheless, ALOS is still ranking well above other global products like SRTM and NASADEM according to quantitative assessments on DEM derived parameters and is still comparable with COP and FABDEM (Bielski et al., 2024; Guth et al., 2024).

The numerical comparisons resulting in Figure 3 can be supported by the graphical representation of the slope differences in Figure 10. Although the spatial distribution of differences varies, larger differences are most noticeable in the ALOS DEM, followed by COP and FABDEM, compared to TINITALY30m, which exhibits fewer differences in slope compared to the reference DEM.

Difference in slope (°)
■ <= -12	■ -4 - 4	■ 12 - 20
■ -12 - -4	■ 4 - 12	■ > 20

406
Figure 10: Difference in slope (degrees) between the four tested DEMs (30m) and the reference LiDAR DEM, by subtracting the LiDAR value from the test DEM value.

TINITALY was originally published with a pixel size of 10x10m. Since the pixel sizes of the open global DEMs selected to be compared with the reference DEM in the AOIb area are around 30x30m, we have decided to conduct the entire analysis using the same grid-cell size of 30m. Therefore, the original TINITALY10m has been resampled to 30x30m cell size. Despite this, the accuracy of TINITALY10m has been also investigated where we have compared the performance of TINITALY30m and of TINITALY10m using normalized differences instead of simple differences. Although this was not the primary aim of the study, the tests indicate that TINITALY at 30m pixel size outperforms the 10m pixel size (Figure 4). These differences in performance, apart from the expected lower uncertainty related to the larger spatial support, may be attributed to the interpolation approach used for TINITALY10m. In areas with low sampling density, noticeable artifacts appear, which can significantly affect the calculation of geomorphometric derivatives. Resampling from the original 10m pixel size to a coarser one (30m) can partially filter out these artifacts. Thus, higher resolution does not necessarily guarantee better results if it is not supported by high-quality elevation data or if it contains a high number of artifacts (Chen et al., 2020; Mahalingam and Olsen, 2016). Additionally, the use of contour lines as input data for TINITALY 10m along with

422 triangulator for interpolation may result in spurious spikes at regular intervals within elevation zones and in areas

423 with triangular slope-faces (Zingaro et al., 2021). Considering the acquisition dates of DEMs in comparison to the

424 LiDAR, COP and ALOS have been surveyed closer to the time of the LiDAR than TINITALY but even so,

425 TINITALY30m has shown better results when compared with the LiDAR. Comparing slope differences in

426 landslide areas across the selected global open-access DEMs, as well as TINITALY10m and TINITALY30m, yield

427 similar results. The graphs in Figure 5 present similar distribution of relative differences in Figure 3 and Figure 4.

428 Comparing slope differences in landslide areas across the selected global open-access DEMs, as well as

429 TINITALY10m and TINITALY30m, yield similar results.

430 The similarity between the geometry of delineated SUs with the same parameters, as compared with the ones

431 delineated from the reference DEM, indicates a higher value of the Jaccard Index for TINITALY30m. This means

432 that the SUs delineated using TINITALY30m most closely resemble those from the reference LiDAR DEM. The

433 remaining of the global DEMs also produce SUs with a high similarity index.

434 In the end of Phase 1, we can conclude that for the Marche region, the use 30m resampled TINITALY DEM is

435 recommended for SU definition, therefore the rest of the analysis proposed for Phase 2 has been based on

436 TINITALY30m.

437 Extending the analysis of SU delineation from AOIb, we have used multiple SU parameters for a more detailed

438 analysis in AOIa with landslide polygons. A landslide can be described as a downslope movement of rock mass,

439 earth or debris (Cruden, 1991). Understandably, slope-facing direction and slope angle can be considered as

440 driving factors for slope failures and can be used to dissect the terrain into units which can morphologically

441 describe landslide prone areas. Landslide susceptibility evaluates the probability of occurrence of a landslide

442 according to a set of variables. Susceptibility depends upon a set of variables whose values are associated in a

443 unitary manner to each mapping unit. Therefore, the mapping unit represents a portion of territory that each

444 variable describes numerically by a single value as if it was a point object. Consequently, the smaller the dimension

445 of the mapping unit, the more representative the single variable is. However, a spatial event such as a landslide,

446 which is a non-point event, does not represent a homogeneous object according to the variables chosen to predict

447 it (i.e., the degree of slope is not homogeneous throughout the landslide area). Thus, to evaluate the probability of

448 occurrence of this event, it is necessary to identify unique values for each chosen predictor calculated within a

449 portion of territory that coincides as much as possible with the landslide. It is also comprehensible that including

450 stable areas, the portion of territory that most closely resembles the landslide area is the slope-aspect which can

451 be represented by the SU. Therefore, to satisfy both the needs described above, the mapping unit should be as

452 concise as possible to describe the shape of the landslide area.

453 The methodology adopted to evaluate the SU subdivision has been designed to address the forementioned

454 requirements by integrating new metrics, specifically tailored for landslide studies considering the relevance of

455 terrain units with landslide inventories. In addition to the aspect segmentation metric (F) proposed by Alvioli et

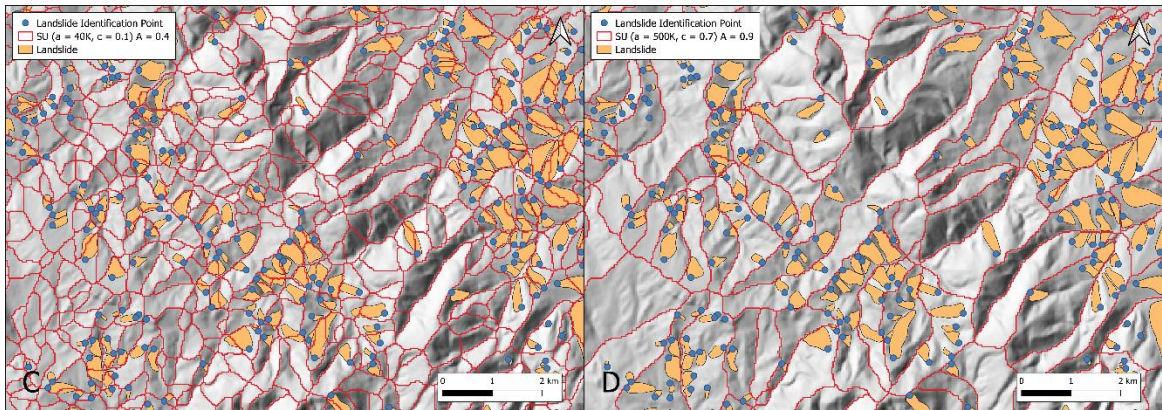
456 al. (2016), the landslide extension coefficient (A) and the landslide density coefficient (D) have also been included.

457 In a way, the F metric can define the shape of the SU on the base of the spatial aspect distribution (Figure 11A

458 and Figure 11B), while a balance between A and D can define the extension of the SU.

According to A, the optimal SUs are the ones that contain the entire landslide, with no landslide area falling in adjacent SUs. The landslide coefficient A may not fully capture the extent of landslide area especially when dealing with landslides characterized by high mobility, as in the case of flow-like landslide which can reach considerable distances where the run-out may move out from the homogenous slope-aspect. Nevertheless, the frequency distribution of the landslide classes in the landslide inventory will balance the A value, therefore the run-out of flow-like landslides may have an impact on the SU dimensions if their presence is significative in the inventory. Otherwise, part of the unstable area may fall in the adjacent SUs. Consequently, the larger the SU is, the higher is the probability of including the entire landslide, as is visible in Figure 11C and Figure 11D where an example of the lowest and highest performing SU partition according to A is represented. In contrast to A, the D metric would avoid the overestimation of the SU dimension which should be limited, ideally, to a single landslide (see the example in Figure 11E and Figure 11F). A correct use of D metric requires that reactivated landslides should be excluded and considered as unique events, to avoid doubling the number of polygons in the same spatial unit.

The variability of the SU extension with respect to the parameters a and c can also be described through the number of unstable units in relation to the total number of SUs. Figure 12 shows how as D increases and A decreases, the unstable units increase. At the same time as D increases and A decreases, the SU extension is reduced and therefore SU count increases.

Metric comparison: F
Metric comparison: A


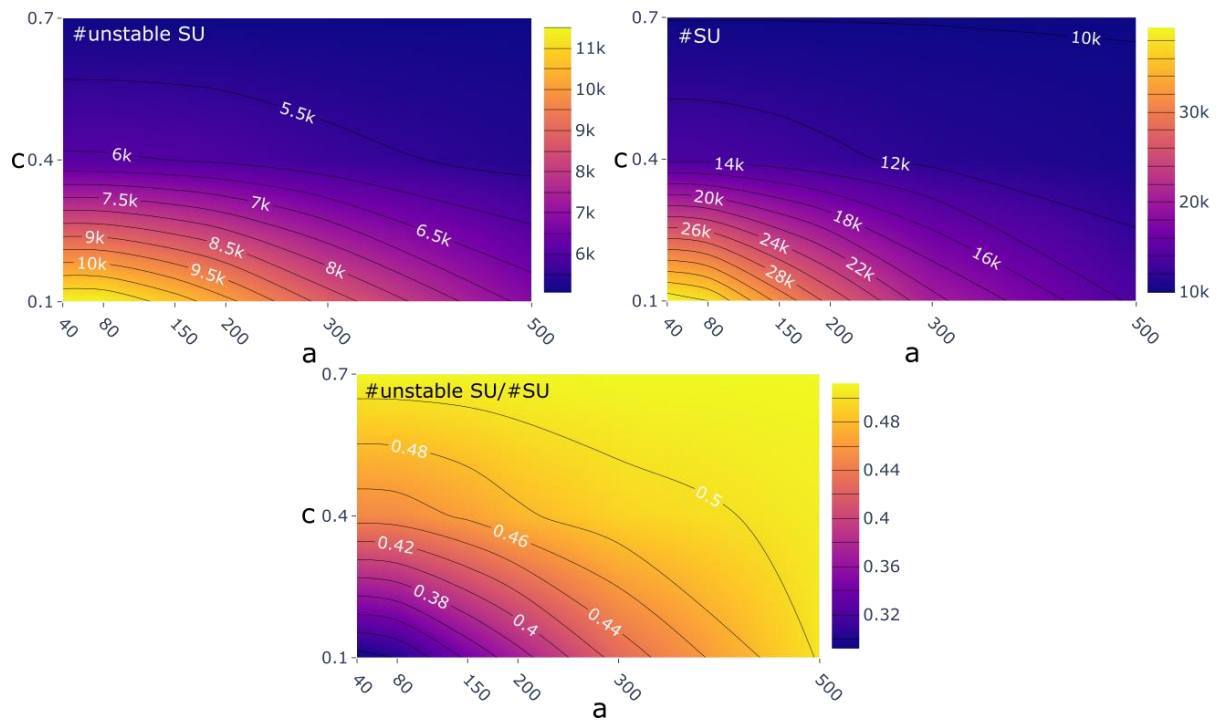
Metric comparison: D
Figure 11: Selection of SUs partition of a sub-portion of the study area AOIa. A) and B) The SUs partitions with the lowest and the highest value of F respectively; C) and D) The SUs partitions with the lowest and the highest value of A respectively; E) and F) The SUs partitions with the lowest and the highest value of D respectively.


Figure 12: Evolution of the portion of unstable SUs in the study area with varying values of *a* and *c*.

All metrics unified in *S* maximizes their effect, as shown in an example in Figure 13 where the comparable differences explain the concept of the ration between the number and extension of landslides contained in the SUs. While it is difficult to minimize SU area as well as contain the landslide area, it is to be considered that the spatial and areal accuracy of landslide inventories can significantly affect the output since the best terrain partition is interpreted based on the dimensions and number of landslide polygons. In this case study, the PAI of Marche region has been used to test the methodology, and while the landslide inventory plays a crucial role, it has to be mentioned that the dataset used may come with limitations. The inventory has not been systematically updated for the mapped landslide areas and the dataset has been updated by reports from scientific literature, local authorities and projects of the municipalities (Costanzo and Irigaray, 2020). Nonetheless, the methodology remains compatible with landslide polygons and SUs supporting the selection of an optimal terrain partitioning.

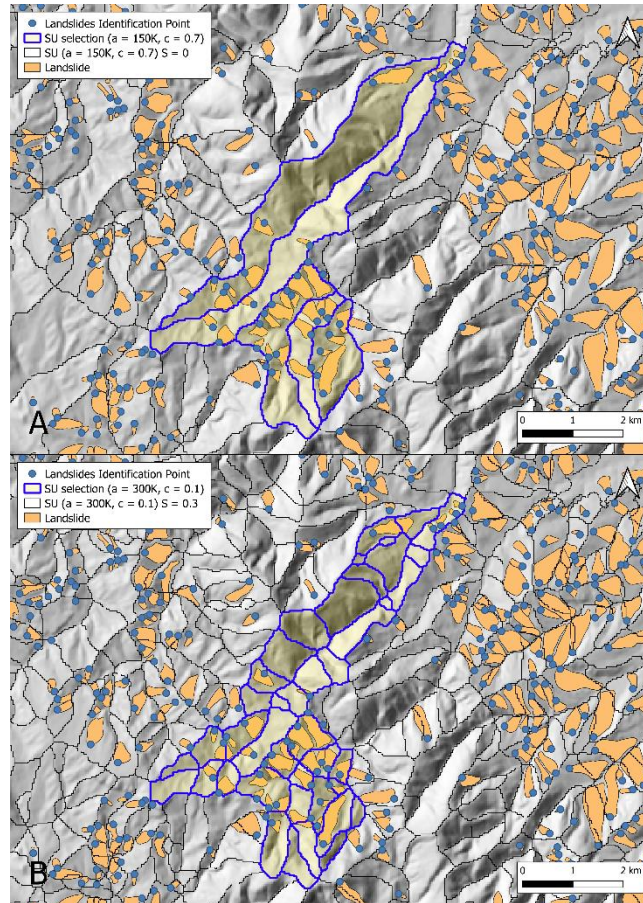
492


Figure 13: SUs partitions of a sub-portion of the Marche study area (AOIa) compared to landslides distribution from the PAI. A) the SU partition (*a:* 150x10³ m² and *c:* 0.7) with lowest value of *S*, B) the SU partition (*a:* 300 x10³ m² and *c:* 0.1) with highest value of *S*.

Two susceptibility analyses have been carried out selecting the S-optimal and S-worst case SUs partitions. Since, the goal of this study is not to assess landslide susceptibility of the Marche region, but to investigate the potential effect of a thought-out SUs delineation for landslide susceptibility evaluated with largely used metrics such as AUC, F1-score and Cohen's Kappa score, the predisposing factors selected for the susceptibility analysis are not entirely representative of the geo-environmental conditions. In particular, not all predisposing factors (e.g., land use, vegetation indices and others) have been considered (see also Titti et al 2024). Therefore, the cross-validation results (Figure 9A) of the susceptibility map (Figure 8A) calculated with the optimal SU subdivision are not performing high in the metrics considered (AUC = 0.68, F1 score = 0.6, K = 0.23 on average). Nevertheless, it is interesting to highlight the trend of the relation between the mapping unit extension and the AUC value along with other metrics.

AUC is calculated as the integral of the ROC curve. The ROC curve depends on the balance between unstable units and stable units in the training dataset, thus, the higher is the ratio between the number of unstable SUs and the total number of SUs, higher is the AUC because higher is the learning capacity of the model to recognize TP mapping units increasing the True Positive Rate (TPR) value of the ROC curve. In the 18 combinations selected, to investigate the highest-performing *a* and *c* values for SUs delineation, we haven't changed the landslide number but the extension of the SUs whose trend is visible through the number of SUs pattern in Figure 14. Considering

512 all the combinations of *a* and *c* performed in our experiment, the higher the extension of the mapping units, the

513 higher the proportion between the number of unstable units and the number of all the mapping units and higher

514 the AUC (Figure 14). Same considerations can be done for the F1 score, and the Cohen's Kappa index whose

515 behaviors follow similar trend of the AUC.

516
517 **Figure 14: Trend of the number of unstable and total SUs comparison (of 18 combinations for *a* and *c*) and the behavior**

518 **of the metrics resulting from the landslide susceptibility analysis. The parameters (*a, c*) are labelled along the**

519 **performance metrics to represent the respective trend.**

520 Therefore, at least in the experiments made for this study, the metrics selected are not suitable for comparing

521 susceptibility maps directly because the training datasets are differently balanced. Nevertheless, a comparison

522 between the S-optimal and S-worst case susceptibility maps, as shown in Figure 8A and Figure 8C respectively,

523 can still be made. Graphically, the maps exhibit a similar spatial pattern of landslide probability of occurrence.

524 This is further supported by the fact that the number of TN units relative to unstable units is nearly the same, at

525 13% and 12% for the S-optimal and the S-worst case, respectively. The primary distinction lies in the susceptibility

526 value, which is on average lower in the S-optimal delineation than in the S-worst case. This difference is attributed

527 to the overestimation of unstable units in the S-worst case due to the imbalance between stable and unstable units.

528 **Conclusions**

529 This study encompasses DEM utilization from the viewpoint of fine-scale morphology and terrain sub-division

530 into mapping units in the frame of regional predictive landslide modelling. The aim is to compare freely available

531 global and national DEMs from which morphological landslide predisposing factors and optimized terrain

532 partition in slope units are derived to map landslide susceptibility. Therefore, the investigation initially identified

533 the optimal DEM among the available ones and then selected the optimal SUs partition in the alternative

534 combinations generated.

535 The global DEMs (ALOS, COP, FABDEM) and TINITALY resampled at 30m have shown considerable

536 differences with respect to the reference DEM (an airborne LiDAR resampled at 30m pixel size) in the selected

537 geomorphometric derivatives in AOIb. Concerning the SUs delineation, the TINITALY30m has shown the best

538 performance thus, it has been selected to generate 18-parameter SUs subdivisions in AOIa. To define the optimal

539 SUs delineation, a novel method has been proposed, which evaluates the SUs alternatives on the base of internal

aspect homogeneity/external heterogeneity, landslides numerosity and landslides extension. According to the S metric (Eq. 6), the SUs partition generated with c equal to 0.1 and a equal to 300×10^3 m^2 results in the optimal subdivision, contrasting with c equal to 0.7 and a equal to 150×10^3 m^2 as the worst case one.

Ultimately, to understand the effect of the terrain partition on the landslide susceptibility model, we have performed the S-optimal and the S-worst case landslide susceptibility. It is understood that the performance metrics (AUC, F1, K) of the landslide susceptibility models do not necessarily equate with the S metric performance. Indeed, AUC, F1 and K depict opposite trends as compared with the S metric.

Though only TINITALY30m has been used in extending the analysis for SU experiments, COP, as the second-best performing DEM for fine-scale morphology, can also be considered in future studies. A holistic comparison could help evaluate its effectiveness in landslide susceptibility studies. Moreover, since the result of the S-method depends on the landslide inventory, further research would pave the way for space-time inventories performing multi-temporal SUs delineations to reach the best terrain delineation for slope failure prediction. Developing space-time landslide inventories and adapting SUs delineation for dynamic, evolving terrains could significantly enhance the predictive capability of landslide models. Ultimately, continued innovation in DEM selection, SU partitioning methods, and landslide inventory development will contribute to more effective landslide risk management strategies and mitigation efforts.

Data availability

The optimal SUs partition of the Marche study area (AOIa) is freely available at Ahmed and Titti (2024).
