Abstract. Probabilistic tsunami hazard and risk assessment (PTHA and PTRA) are vital methodologies for computing tsunami risk and prompt measures to mitigate impacts. At large regional scales, their use and scope are currently limited by the computational costs of numerically intensive simulations behind them, which may be feasible only with advanced computational resources like high-performance computing (HPC) and may still require reductions in resolution, number of scenarios modelled, or use of simpler approximation schemes. To conduct PTHA and PTRA for large proportions of the coast, we therefore need to develop concepts and algorithms for reducing the number of events simulated and for more efficiently approximating the needed simulation results. This case study for a coastal region of Tohoku, Japan, utilises a limited number of tsunami simulations from submarine earthquakes along the subduction interface to build a wave propagation and inundation database and fits these simulation results through a machine learning-based variational encoder-decoder model. This is used as a surrogate to predict the tsunami waveform at the coast and the maximum inundation depths onshore at the different test sites. The performance of the surrogate models was assessed using a 5-fold cross validation assessment across the simulation events. Further to understand its real world performance and test the generalisability of the model, we used 5 very different tsunami source models from literature for historic events to further benchmark the model and understand its current deficiencies.

1 Introduction

Tsunami are potentially one of the most devastating natural hazards impacting life, property and the environment. More than 250,000 casualties and USD 280 billion damage were caused by tsunami worldwide between 1998 and 2017 (Imamura et al., 2019), with the 2004 Indian Ocean and 2011 Tohoku tsunami events responsible for most of these losses. Tsunami hazard and risk assessments are fundamental in disaster management, as they facilitate the effective management of coastal regions and communities at risk of experiencing a tsunami (Mori et al., 2022). The results of tsunami hazard and risk assessment help plan and prioritise local and regional hazard mitigation efforts like land use and management, the engineering design of protective structures and buildings, tsunami monitoring and early warning systems, evacuation plans, and emergency response.

The simulation-based tsunami hazard analysis workflow consists of modelling different processes of the tsunami life cycle - generation, propagation and inundation (Behrens and Dias, 2015; Marras and Mandli, 2021) as depicted in Fig.1. Each of these tsunami processes requires forward numerical modelling at different spatial scales, with varying complexity and different
numerical schemes. Many of these steps are computationally demanding and a substantial number of such simulations may be required in tsunami hazard analysis.

There are two broadly categorised approaches to tsunami hazard and risk assessment (Mori et al., 2018): deterministic and probabilistic approaches. The deterministic approach aims to study a select number of large tsunami scenarios, such as a past historical event or the possible worst-case events. This approach has been most widely used as it requires fewer events to simulate and hence less computational effort. With only a single or limited number of tsunami scenarios modelled, we can estimate a tsunami hazard metric for the given scenarios, such as wave height at an offshore site, or inundation depth, run-up, etc. at an onshore location of interest for each scenario. Such results are easy to communicate and are useful in conservative decision-making activities such as evacuation planning. Instead, the probabilistic approach involves modelling a large number of possible tsunami events typically in the range of thousands (Gibbons et al., 2020) to million (Basili et al., 2021; Davies et al., 2018) to estimate the exceedance rate of the said tsunami hazard metric at a location or region of interest (Geist and Parsons, 2006; Grezio et al., 2017). This approach is complex and computationally demanding but allows the possibility of exploring different sources of uncertainty and making risk-informed decisions. When linked with fragility and loss models, probabilistic estimates of potential damage or loss of life and property are obtainable (Goda and De Risi, 2017).

Figure 1. The sequence of a tsunami from the deep ocean generation and propagation, shallow coastal-zone shoaling, coastal inundation and interactions with the built environment, and the methods used to model each part of the sequence. The red dotted lines depict the interface between the tsunami forward modelling steps where different models can be coupled or linked.

The large computational burden from the many simulations needed in probabilistic tsunami modelling can limit their application, especially for onshore tsunami hazard and risk assessment where modelling of inundation processes is vital (Lorito et al., 2015; Grezio et al., 2017). Accurately simulating the tsunami wave shoaling process nearshore and the resulting inund-
tion onshore necessitates the use of a 2D nonlinear shallow water equation (NLSWE) model at resolutions finer than at least 100m on land. For scenarios where modelling turbulent tsunami forces onshore with precision is essential, a 3D Navier–Stokes Equation (NSE) model proves to be suitable (Marras and Mandli, 2021). Importantly, both the 2D NLSWE and 3D NSE models come with higher computational costs, exhibiting an exponential factor in comparison to the more computationally efficient 1D linear shallow water equation (LSWE) model commonly employed to model tsunami wave propagation in deeper oceanic regions. Figure 1 represents the off-to-on-shore tsunami forward modelling flow and the input-output links of the machine learning surrogates.

To handle or overcome this computational challenge of scale and the need to model a large number of events, various methods have been adopted (Behrens et al., 2021):

1. Reduce the number of events to be modelled, using sampling techniques, clustering, and other selection methods (Lorito et al., 2015; Williamson et al., 2020; Davies et al., 2022)

2. Approximations of results using methods like Green’s Function, amplification factors, and reduced complexity models (Molinari et al., 2016; Løvholt et al., 2016; Glimsdal et al., 2019; Gailler et al., 2018; Grzan et al., 2021; Röbke et al., 2021)

3. Hardware and computational improvements like a nesting of grid domains, adaptive variable grid resolution, parallelisation and GPU-based acceleration, coupled multi-scale modelling, exascale codes (LeVeque et al., 2011; Shi et al., 2012; Oishi et al., 2015; Macías et al., 2017; Marras and Mandli, 2021; Folch et al., 2023)

4. Surrogates using statistical emulators and machine learning models (Sarri et al., 2012; Salmanidou et al., 2021; Mulia et al., 2018; Fauzi and Mizutani, 2019; Makinoshima et al., 2021; Fukutani et al., 2021, 2023; Lee et al., 2023)

Running the numerical simulations, especially for modelling the tsunami inundation with an NLSWE model takes a lot of time and computational resources, for example accounting for about 13,600 GPU hours in the local PTHA study for Catania by Gibbons et al. (2020), refer Table S5 for runtimes of this study. Among the different approaches to reducing such computational and time burden, surrogates can provide an instantaneous approximation to the output of the numerical simulation. Surrogates are fit (trained) on a set of model inputs and outputs, called training data, to derive a mathematical or statistical relationship between the inputs and outputs; this provides a fast solution to otherwise time-consuming numerical simulations but may introduce some acceptable errors. Surrogates such as statistical emulators, can be fitted using a small training dataset built using a limited number of simulations. The application of such surrogates in tsunami modelling has been used for uncertainty quantification or sensitivity analysis (Sarri et al., 2012; de Baar and Roberts, 2017; Kotani et al., 2020; Salmanidou et al., 2021; Giles et al., 2021; Tozato et al., 2022) and hazard assessment (Fukutani et al., 2021, 2023; Lee et al., 2023), which are generally difficult to conduct in a brute-force approach where one would need to simulate all possible events explicitly or in a real-time time setting where running high-fidelity models in limited time is difficult. Another type of surrogate used are the machine learning models (referred to as ML surrogates herein), which are also trained on the available input-output datasets using a supervised learning framework. Tsunami ML surrogates in comparison to statistical surrogate models, especially those
based on deep neural networks, utilise a large training dataset to optimise the model parameters using backpropagation. This may require a much larger number of numerical simulations to create the relevant input-output datasets for training or fitting such a model. Using such a framework to prediction of a real-time tsunami is feasible and widely proposed for faster than real-time forecasting and early warning purposes (Mulia et al., 2018; Fauzi and Mizutani, 2019; Liu et al., 2021; Rodríguez et al., 2022; Kamiya et al., 2022; Mulia et al., 2022; Wang et al., 2023) especially with inputs derived directly from real-time sensors (Makinoshima et al., 2021; Mulia et al., 2022). See Table 1 for a comparison of different surrogate classes.

Models of varying complexity and resolution, as depicted in Fig.1 are often coupled to accurately simulate the generation and propagation of tsunamis from the deep ocean to the near shore and inundation onshore (Abrahams et al., 2023; Son et al., 2011). For probabilistic tsunami modelling with a large number of events, the typical approach is to use outputs of a given model level as boundary conditions to the next model in forward modelling flow, taking advantage of each model’s varying complexity, resolution, and computational efficiency. In this study, a hybrid modelling framework is introduced (see Sect. 2). We suggest using a limited number of full simulations to build or train a tsunami ML surrogate and completing the most computationally demanding phases of tsunami forward modelling for the remaining events as direct final modelling using the ML surrogate. Figure 1 compares the different methods used in traditional tsunami forward modelling chains and as an alternative different connections for the setting up of a surrogate in the form of statistical emulators and machine learning models.

This framework recognises several key concepts, including reducing the number of events for numerical simulation, modular multi-scale modelling, and the use of machine learning-based surrogates for hazard approximation. By combining these ideas, the proposed framework provides a comprehensive approach to enhance the modelling process and efficiently achieve the final results. Many of the models and datasets needed in this framework are already available; we discuss how to put them together in a workflow and build the ML-based surrogate for the final tsunami modelling. Further, we conduct experiments to check the skill and usability of an ML surrogate for tsunami hazard approximation nearshore and onshore.

The current challenge lies in the need for an extensive size of the training dataset generally required by ML surrogates in tsunami modelling for training to generate accurate predictions. While they provide instantaneous results, the cost of developing the training data set for the machine learning surrogates may outweigh the benefit of instantaneous prediction. When ML models are not appropriately trained to understand the underlying physics or dynamics of the tsunami and use small training dataset, they may overfit and struggle to generalise well beyond the training data(out-of-training situations) (Seo, 2024).

To overcome this dependence on a large training size, our ML surrogate exploits the ability of the encoder-decoder network in dimensional reduction, feature representation, and sequence-to-sequence transformation for approximating tsunami hazard nearshore and onshore. We use tsunami data from a small set (about 500) of simple earthquake rupture scenarios which may provide a sufficient learning basis for the ML surrogate. We describe how a variational encoder-decoder (VED), a type of neural network model (see Sect.2.2.2), is trained to take the tsunami waveform at points where offshore depth is 100 m as input and predict the tsunami waveform at nearshore points with depths of 5 m and maximum inundation maps onshore for three different locations along the coastal Tohoku region in Japan. Thus, skipping the computationally demanding modelling of non-linear processes in the shallow water regions nearshore and the inundation processes onshore for a given tsunami event.

We check the generalisation ability of this model by testing the prediction error for a set of finite-fault rupture events of historic tsunami scenarios to evaluate the efficacy of this hybrid modelling approach.

## 2 A framework for approximating tsunami hazard nearshore and onshore at reduced computation cost

![Diagram of framework](image)

**Figure 2.** Overall framework for the nearshore and onshore hazard approximation using ML surrogate

Our framework employs a hybrid modelling approach that integrates physics-based numerical simulation and data-driven machine-learning models for tsunami hazard approximation. By combining the strengths of these models, we aim to represent the tsunami hazard for a coastal site of interest as the time series of the tsunami wave height near or along the shore and the max inundation depth onshore within a reasonable computational budget.

This section discusses the various components of the proposed framework as seen in Fig. 2. The first step is the generation of synthetic data which is needed to train the ML surrogate model. This requires the full forward modelling of the tsunami generated from simple earthquake sources discussed in the design of events and recording the tsunami water level time series for such events at different depths, at 100 m depth and 5 m depth near shore, and the maximum inundation depth onshore for the event using an NLSWE tsunami model setup.

The second step is the development of the machine-learning models for use as the ML surrogate, whose outputs are the nearshore tsunami height time series and the onshore maximum inundation depth. In the current study, the framework is applied...
and tested by comparing the prediction of the surrogate machine learning models against results from numerical simulation for a portion of the synthetic events as hold-out testing and historic events for generalisation testing.

## 2.1 Generation of Synthetic Data

The characteristics of tsunamis in a region are intricately tied to factors such as earthquake sources and their recurrence, ocean bathymetry, shelf profile, coastal topography, and man-made structures like coastal defence and urban infrastructure. The rarity of tsunami events and the limited availability of comprehensive observational records across the coastal region make it impossible to construct a robust dataset for training and testing a machine-learning model using purely historic observations. Due to this data limitation, we instead attempt to create a diverse dataset for training and testing the ML surrogate to effectively capture the wide spectrum of tsunami dynamics in a region. The idea is to simulate earthquakes of different magnitude, different locations, with different slip amounts and rupture geometries generating tsunami waves of different amplitude and wavelengths offshore, causing inundation of varying patterns and extents onshore.

Thus, we model a wide variety of earthquake scenarios discussed in Sect.2.1.2 using a tsunami hydrodynamic model created for the Tohoku region (Sect.2.1.1) covering three test sites.

### 2.1.1 Tsunami model and test locations

Three locations with different coastal configurations are identified for this study – Rikuzentakata (enclosed bay), Ishinomaki (shielded), and Sendai (open bay) – where different coastal processes like shoaling, refraction, reflection, and resonance are expected to impact the tsunami nearshore results and provide varied settings for testing the proposed methodology of developing an ML-based surrogate.

For the simulation of the synthetic events, and recording their offshore waveform (water level time series) and onshore flood inundation depths, a tsunami model based on GeoClaw Version 5.7.1, (Clawpack Development Team, 2020) was developed. This GeoClaw model covers the Pacific Side of the Honshu island and solves the depth-averaged NLSWE using adaptive mesh refinement using rectangular grids in the geographic coordinate system (latitude and longitude) for the base Level 0 at resolution 0.01215 degrees.

The adaptive mesh refinement ranges from level 1 of resolution 0.006075 degrees for the overall model domain, Level 2 of resolution 0.00405 degrees at bathymetric depths around 100 m to 850 m and level 3 of resolution 0.00135 degrees for bathymetric depths less than 100 m as in Fig.3a. An additional refinement is enforced for the three test sites resulting in the finest grids of 0.00045 degrees roughly equivalent to 50 m in resolution for capturing the inundation onshore as seen in Fig.3b.

The model uses topographic data from the Japan cabinet project available in 1350-450-150-50m resolution, the final 50 m resolution grids of this dataset were superimposed with COP-DEM, a Digital Surface Model (DSM) representing the elevation of the Earth’s surface including buildings, infrastructure and vegetation with native resolution of 30 m, and a coastal tsunami defence elevation dataset also available from the cabinet project for representing the onshore elevation more realistically for the tsunami inundation modelling.
The virtual gauges are set at depths of 5 m and 100 m as shown in Fig. 3b to record the elevation of water level at regular time intervals and fixed grid monitoring is used to record the maxima of the inundation depths from each event for the three coastal regions for each tsunami simulation. Each tsunami simulation is run for a 6-hour duration from the onset of the tsunami. Tides and wave components are ignored and the initial water level condition is set at zero mean sea level to consider a still ocean condition.

The model was tested and calibrated using the 2011 Tohoku historical event’s gauge and inundation survey data, see results available in Supplements Fig.S1 and Fig.S2.

![GeoClaw Domain](image1)

![Test site with virtual gauges](image2)

**Figure 3.** (A) Tsunami model coverage and adaptive grid resolution system (B) Virtual Gauges and inundation sites.

### 2.1.2 Design of experiments (DOE)

The design of the experiment consists of a total of 559 events of two categories of rupture, distinguished by their geometry and slip distribution: (a) Type A - ruptures represented by a single rectangular planar surface with homogeneous slip and (b) Type B - ruptures that combine numerous smaller rectangular planar surfaces (i.e., sub-ruptures), each of which has homogeneous...
slip, such that the rupture surface can bend and the slip distribution can be heterogeneous. We calculate 383 hypothetical
tsunamigenic earthquakes of Type A with moment magnitude ranging between 7.5 and 9.0 at an interval of 0.5 and uniformly
distributed over the Tohoku subduction interface earthquake source, see Fig.4b. The $M_w$ 9.0 events are restricted to locations
at depth shallower than 16 km with respect to the top centre of the fault along the subduction interface. Such events cause
unrealistic amount of uplift on large portions of land and are unlikely to cause tsunami at such depths.

Further, 176 Type B multi-fault earthquakes are created using a combination of 6 to 12 sub-ruptures of length 100 km and
width 50 km as in Fig.4c are created, with $M_w$ 8.68 - 9.08 and distributed along the shallow section of the Tohoku subduction
interface, where the bottom centre are at the depth between 17-28 km. The slip distribution of the fault segments is modelled
as a skewed normal distribution where the average combined slip value is between 10 and 25 m. Information on depth, slip,
strike, and dip (see Table 2) is derived from the Slab2 model of the Japan trench (Hayes et al., 2018), and the rake is always set
at 90 degrees (Aki and Richards, 2002).

The seafloor deformation is analytically modelled assuming homogeneous slip for the rupture or sub-ruptures using Okada
solution (Okada, 1985) with the value of rupture length, width, and slip scaled based on the magnitude of the event (Strasser
et al., 2010). We consider that the coseismic displacement is instantaneous and equivalent to the sea surface displacement to
generate the tsunami. This initial sea surface displacement is modelled to match the base resolution of the tsunami model at
0.01215 degrees grids.

Table 2. Earthquake rupture parameters for Type A and Type B, the rake value is always 90 degrees.

2.1.3 Test Events

Along with using a random subset of the events from the design of experiments, we additionally model a set of 5 events to
evaluate the performance of the machine learning model. This is to test the model over a generalised dataset which is different
from the training dataset used in building the model. The numerically simulated tsunami are known to be sensitive to the
earthquake slip, fault geometry, rupture mechanisms, and the discretisation used (Gibbons et al., 2022; Goda et al., 2014)
and their resulting wave profile, direction, and inundation may vary significantly. Although there is significant variation in
the characteristics of the different tsunami events generated in the design of experiments to train and test the ML surrogate,
we add these additional historic test events with complex heterogeneous slip, events with instantaneous and time dependent
slip displacement and events located beyond the Tohoku source region used for training, as seen in Fig.3. These include the
following events described below.
1. 2011 Tohoku Earthquake:
   – Test A (instantaneous displacement) using Fujii et al. (2011)
   – Test E (time-dependent displacement) using Yamazaki et al. (2018)

2. 1933 Sanriku Earthquake:
   – Test B (outer rise event with normal faulting) using Okal et al. (2016)

3. 1896 Sanriku Earthquake:
   – Test C (outside Tohoku source region considered in DOE) using Satake et al. (2017)

4. 1968 Tokachi-Oki Earthquake:
   – Test D (outside Tohoku source region considered in DOE) using Riko et al. (2001)

2.2 Machine Learning Model

Previous works (Fauzi and Mizutani, 2019; Liu et al., 2021; Makinoshima et al., 2021; Núñez et al., 2022; Mulia et al., 2022; Rim et al., 2022) that focused on using ML models for use in tsunami forecasting and early warning needs have also used neural networks in the form of CNN and MLP models. These models are usually trained to take short duration (20 - 30 min) inputs.
from sensors like offshore ocean bottom pressure sensors and geodetic sensors (GNSS) for their tsunami hazard prediction. This is due to the constraints of a short lead time in the event of a tsunami. Furthermore, the tsunami observation network is designed with a given earthquake source region in focus, leading to the design and training of the ML model which is constrained to a very specific regional and source setting.

In contrast, we discuss two ML surrogate models in this work with the main difference being the output of the model: either a time series of the water surface elevation or the maximum inundation depth across a set of onshore locations. The design of the ML model or surrogate for the current framework focuses on:

1. The model architecture, that should be able to train and fit with a relatively small number of events such that it can serve the purpose of solving the computational constraint for its use as a surrogate model.

2. The model has a balanced performance, it can predict the hazard sufficiently well for small and large-magnitude events across the domain of interest.

3. The model training is not sensitive to training datasets, that is, it should not overfit the data and should be capable of predicting results for different ruptures as long as the offshore water level amplitude is available.

4. The model design should be able to connect easily with available outputs from other regional propagation models and be easily replicated across different coastal configurations.

### 2.2.1 Data preparation

The machine learning model in this study uses two types of datasets from the tsunami simulations: (a) tsunami waveforms - water level time series and (b) maximum inundation depth map. Figure 6 provides a summary of the dataset for the three test locations - inundation depths, area and maximum amplitude at the virtual gauges.

For each of the events, we process the simulated water level time series at the virtual gauges and the maximum inundation map in the following steps. All events where the tsunami water level does not cross a set threshold of 0.1 m at the selected deep
Figure 6. Box plot showing variability in the offshore and nearshore gauges and the inundation properties for the three test sites.

Offshore virtual gauges of 100 m depth and 0.5 m at the shallow nearshore virtual gauge of 5 m depth are ignored as they result in negligible tsunami inundation.

At the instance of a time when this threshold is crossed at the shallow gauge, an observation time window of 240 minutes is selected to calculate a uniformly sampled wave amplitude time series with 1024 data points. As many of these local source events cause significant local deformation to the bathymetry, which is captured in the and water level time series. This offset is removed from the time series data at both nearshore and offshore virtual gauges (e.g. Fig.7) as a preprocessing step for reducing the complexity in the dataset which can help in training the model.

In the case of the maximum inundation maps, all grid points that are flooded across the entire simulation dataset of all the modelled events are selected as a fixed set of locations, and the maximum inundation for each event at each such location is stored as a 1D array. This yields 6648 grid points for the Rikuzentaka area, 54671 grid points for the Ishinomaki area, and 129941 points for the Sendai area.

2.2.2 Variational Encoder-Decoder (VED) - Model architecture and training approach

Our design of the "VED" architecture extends upon existing statistical and ML models used for tsunami forecasting and rapid modelling. Mulia et al. (2018) used the feature space from the principal component analysis (PCA) as a form of dimensional reduction to search the closest inundation map from a large simulation database against results from a quick low-resolution simulation and interpolate new high-resolution results using these samples. Machine-learning-based approaches that are trained on tsunami simulation databases, in particular convolutional neural networks (CNN), have also been used to predict the full-time series of the water level elevation using sparse observational inputs (Liu et al., 2021; Makinoshima et al., 2021; Núñez et al., 2022). In the case of prediction for maximum inundation depth maps, a fully connected or dense layers have been used to efficiently map the output across the large set of locations as in Fauzi and Mizutani (2019); Mulia et al. (2020, 2022).

The deep neural network models used in the above work for tsunami predictions typically need a large number of training examples to learn a useful representation and avoid overfitting the parameters of their different layers. Certain model archi-
Figure 7. Correction of the waveform by removing the deformation and the selection window of 4 hours based on offshore gauge crossing threshold of 10 cm.

Figure 8. Location of grids affected from the DOE simulation and for one of the test events.

Figure 8. Location of grids affected from the DOE simulation and for one of the test events.
tectures and training schemes can help them become more learning efficient, generalise better, and provide higher prediction performance. One such approach is encoding-decoding, a class of supervised machine learning aimed at training a neural network to learn a lower-dimensional representation of the input that can be used to construct the output. It consists of three parts: encoder, latent variables, and decoder.

\[ z = f(w_f, b_f, x) \]  

(1)

\[ y = g(w_g, b_g, z) \]  

(2)

Figure 9. Schematic of a Variational Encoder Decoder

The encoder function \( f(\cdot) \) with its learnable parameters, weights \( w_f \) and biases \( b_f \) maps the input data \( x \) to a reduced number of latent variables \( z \) and a decoder function \( g(\cdot) \) with its learnable parameters, weights \( w_g \) and biases \( b_g \) maps the latent variables \( z \) back to the high dimensional data space as the construction of the output \( y \) see Eq.1 and 2. The encoder-decoder(ED) is trained to minimise the reconstruction error between the input data and the output of the decoder network using backpropagation optimisation. Similar to Liu et al. (2021) we use convolutional layers and variational encoding; see Fig.9. The encoding convolutional layers and max pool operations of the encoders perform dimensionality reduction on the time series data at the input gauges similar to a principle component analysis (PCA) of Mulia et al. (2018) and in inverse the
decoding transposed convolutional or dense layers performs the necessary transformation to predict the output time series or multi-location inundation depths, see Tables S1 and S2.

Variational encoding maps the input data to the probabilistic distribution of the latent variables $z$, this makes VEDs more flexible in capturing the underlying data distribution and modelling the epistemic uncertainty in the input encoding process. Compared to a deterministic encoder, the latent space is mapped as continuous and smooth variables, making for a more interpretable and structured representation of the data in the encoding latent variables Liu et al. (2021).

We use two VED models as the ML-based surrogates, to predict the water level time series (waveform) at a gauge location and the flood inundation footprint in the form of the maximum inundation depth. Early in the study we evaluated the prediction of two inundation parameters - maximum inundation height and maximum inundation depth, with the model predicting the maximum inundation depth better. We do not discuss the result for the maximum inundation height in the study. The models receive its input $x$ in the form of a stack of time series from the selected offshore gauge/s, which is encoded into the latent variables $z$ by four convolutional layers with kernel size 3 and padding 1 using a Leaky ReLU (0.5) activation which helps introduce non-linearity and prevent vanishing gradient during training. After each convolutional layer, we perform a max-pooling operation to reduce spatial dimensions on the feature maps. The choice of the number of layers, channels, kernel size and the input data sampling rate are interdependent and were decided by testing multiple configuration, Tables S1 and S2 describes the two surrogate architectures used in the study. For the encoding in the onshore VED model, we additionally apply batch normalisation after the first max pooling layer to help stabilise the training as we use a single batch training and a dropout layer with a rate of 0.1 is applied after the final max pooling layer as additional regularisation, refer other operations in S2.

The latent variables $z$ are encoded as the mean and sigma values of a Gaussian distribution using a reparametrisation method (Kingma and Welling, 2014).

The decoding layers take the sample from the latent space and reconstruct the outputs. For near-shore VED, to predict the nearshore time series of the water level, we adapt the encoder architecture in reverse using four transposed convolutional layers. For the onshore VED, to predict the max inundation depths we use a dense layer that maps the sample from the latent space to the outputs i.e. the max inundation depth directly. The model hyperparameters including the number of latent variables, a learning rate of 0.0005, and no weight decay, were chosen through rough experimentation to achieve optimal results. Table 3 summarises the size of input, output, and latent variables used in the two surrogate models. Supplements Table.S1 and Table.S2 provide more information on the model layers and operations used in the two surrogate models.

The loss function used to train the models comprises two components: the prediction loss and the Kullback-Leibler (KL) divergence loss. The prediction loss measures the difference between the constructed data to the output data in terms of the mean squared error. The KL divergence loss (Kingma and Welling, 2014; Liu et al., 2021) encourages the latent space distribution to be close to a unit Gaussian distribution, acting as a regularisation term. This additional regularisation also helps prevent overfitting and improve generalisation. The components of the loss function in Equation 3 can also be weighted to improve the overall model prediction.
Total Loss = \frac{1}{2} \sum_{i=1}^{n} (y_i - \hat{y}_i)^2 + KL(q(z|x)||p(z)) \quad (3)

Given the relatively small size of our training dataset, we employ K-fold cross-validation with five folds to fully use the available data set for training and testing. This helps in assessing the model’s generalisation ability and sensitivity to overfit with such limited training information. We conducted the training in a single batch. This approach differs from conventional training settings, where mini-batch training is adopted to handle large training datasets. The single batch approach allows the model parameters to be optimised using the entire fold’s dataset in each training iteration, effectively leveraging all available information to update its parameters. This strategy helps prevent the model from memorising the training data or overfit while facilitating convergence.

Applying an ensemble approach to the prediction, we use the variational encoding 9 to generate 100 sample predictions for each test event of the fold. Further, when generating prediction for the historic event in 2.1.3 we use all the five models trained as part of the 5-fold cross validation to generate 5 x 100 predictions, thus using the overall dataset for model training and prediction for these test events.

3 Metrics for evaluation

To assess the general fit between the observed and predicted values, the mean squared error (MSE), the coefficient of determination \( R^2 \), and the goodness of fit \( G \) are used. MSE quantifies the average squared difference between observed and predicted values, with lower values indicating better model performance. \( R^2 \) measures the proportion of variance in the dependent variable (observations) that is predictable from the independent variable (predictions), providing information on the accuracy of the model based on the correlation or dependence between observations and prediction, with high values close to 1 indicating a good result. \( G \) is used as a cost function to measure the disagreement between observed and predicted values, considering both the magnitude and direction of the deviations, with a lower value close to 0 being better. Lastly, we used the

In the case of the nearshore surrogate, where accurately predicting the peaks and their timing is crucial, Relative Peak Deviation (RPD) and Maximum Peak Delay (MPD) are used. RPD measures the relative difference between observed and predicted peak values, providing insight into peak accuracy. MPD evaluates the time delay between highest observed and predicted peaks, crucial for assessing the timing accuracy of peak. For the onshore surrogates, where accurately predicting inundation extents and depth is the focus, the accuracy score quantifies the proportion of correctly predicted inundation extents relative to the total number of observations. This metric provides a clear indication of the model’s predictive performance in accurately mapping inundation for depths above the threshold of 10 cm or a select depth class (say 0.1 m to 1 m). These metrics collectively offer a comprehensive evaluation of the ML surrogate’s prediction.

4 Results

4.1 General fit

As a first step, we evaluate the sensitivity of the learning or parameter optimisation to the training data as part of the five-fold cross-validation study. The mean square error values are summarised in Table 5 for each of the folds. For the nearshore surrogate (predicts the time series) it ranges between 0.042 - 0.197 and for the onshore surrogate (predicts the max inundation depth map) it ranges between 0.169 - 1.129 at the three test sites. We also record the maximum elevation values from both the surrogate for each test event in Sect.2.1.2 and compare it with the true values of the GeoClaw tsunami model described in Sect.2.1.1 using the scatter plots of Figures 10 and 11. The predictions are in good agreement, well correlated with the true values and lay close to the true line. In case of the nearshore surrogates, we notice larger uncertainty for Sendai compared to the other test sites, while for the onshore surrogates, Ishinomaki has more uncertainty. The plot also marks the prediction for the five historic test events, discussed further in Sect.4.4. The prediction of the maximum elevation for the waveforms and...
the maxima of the maximum inundation depth show good fit with little underestimation or overestimation (Figures 10 and 11) and highlight the generalisation of the model across unseen data.

Figure 10. Prediction of the maxima water level from the nearshore surrogate for the training, test and historic events

4.2 Nearshore Approximation

The nearshore surrogate predicts waveforms of 4 hr duration; the time series predictions for gauge 6042 at Rikuzentakata, gauge 5675 at Ishinomaki, gauge 5440 at Sendai for five random events from the fold 0 test set are shown in Fig.12. These figures show the mean prediction along with the 2 standard deviation uncertainty bands for all the three gauges. This uncertainty represents the epistemic uncertainty of the machine learning model from a variational latent space. They show good agreement with the observations, but the true observation does not always lie within the uncertainty band, as seen in event 319 at Rikuzentakata. Furthermore, the uncertainty range provides a useful indicator of the stability and sensitivity of the selection.
Figure 11. Prediction of the maximum inundation depth from the onshore surrogate for the training, test and historic events of model parameters and latent variables. We also evaluate the performance of the mean prediction using the evaluation metrics for the time series in Table 4. There is a relative peak deviation of up to 0.2 and a maximum peak delay of up to 2 hours when the magnitude of the highest peak is not captured accurately.

Figure 12. Prediction examples from the nearshore surrogate for the DOE test events.
4.3 Onshore Approximation

With the onshore surrogate we predict the maximum inundation depth at the selected grid location for the three test sites. The prediction maps at Rikuzentakata for five events from the fold 0 test set are shown in Fig.14. We plot the true observed values from the GeoClaw simulation and the mean predictions of the surrogate in columns 1 and 2. The misfit between true observation with the mean prediction and +/- 2 standard deviation values are plotted in columns 3-5. The uncertainty in the onshore surrogate leads to variability in both the mapped inundation area and the water depth at each grid location for the predictions. This uncertainty depends on the machine learning parameters and the latent variables. The predictions show good agreement with the observations, though there is a tendency of the having some artefact flooding, i.e. to predict inundation at grids disconnected from the main flood extent which is an unphysical characteristic of the surrogate. Similar maps for Ishinomaki and Sendai are made available in the Supplement Figures S3 and S4.

We also evaluate the performance of the mean prediction +/- 2 standard deviation using the evaluation metrics for the time series in Table 4. The accuracy score (A) focuses on the identification of the flooded area with depth greater than 10 cm or not, while the goodness of fit (G) provides an assessment of the correct prediction of the maximum inundation depth for the location with depth greater than 10 cm. Across the different test events and ensemble predictions, 93.397% have an accuracy score greater than 0.9 and G values less than 0.1. The spread of the G and A values for different depth classes are plotted in Figures 16a and 16b.
Figure 14. Prediction examples from the onshore surrogate at Rikuzentakata for the DOE test events. (Basemap from ESRI World Imagery)
Figure 15. Historical prediction from the onshore surrogate at Rikuzentakata. (Basemap from ESRI World Imagery)
4.4 Generalisation Ability: Predicting historical test events

Generalisation of the machine learning surrogates ensure that they would perform well on unseen data by capturing the underlying characteristics of the data rather than memorising and over fitting on the training data. To test the generalisation we examine the prediction for the historical test events described in 2.1.3. These results are the predictions using all five VED models trained on different data subset in the cross-validation exercise, providing a wider ensemble with 500 predictions compared to the 100 predictions from a single VED model in the previous section.

Figure 13 plots the time series prediction for these events for the three regions, similar to the fold test events in Fig.12. Compared to the results of the fold test events previously described, the peak values and their timing are well captured across the test sites and events. As observed earlier the G values tend to be higher than desirable for the smaller events (B, C and D). The surrogate is unable to predict the high frequency characteristics (event B and C) but is able to capture it in the uncertainty bands of the waveform ensemble. When comparing the mean prediction with the true observation, the G values range between 0.054-0.225 for Rikuzentakata, 0.071-0.442 for Ishinomaki, and 0.07-0.411 for Sendai. Similar to the prediction from the test fold, underestimation in some of the wave peaks result in the MPD of up to 107 min and 65 min in Rikuzentakata and Ishinomaki, respectively, and 193 min in Sendai.

Figure 15 plots the inundation map for Rikuzentakata similar to the fold test events shown in Fig.14. For the large magnitude 2011 Tohoku events (test events A and E) the accuracy metric for the flood mapping is high: 0.9 using the mean prediction for event A and 0.93 for event E. However, there is significant under-prediction in flood depth and misfit up to 5 m. For the smaller magnitude events related to the Sanriku events (test events B and C), there is overestimation in the flood mapping, with many locations having predictions of small depths resulting in lower accuracy metric of 0.83 for event C and 0.65 for event B. For the 1933 Tokachi-Oki event (test event D), accuracy in flood mapping is high with a value of 0.96, but flood depths are underestimated with a low G value of 0.623.

For Ishinomaki the prediction performs well in characterising the small events in terms of the depth and area flooded. There is an underestimation in flood depths and mapping area for event A and an overestimation in flood area for event E. For Sendai the accuracy in the flood mapping footprint is high but significantly underestimated in the prediction of the flood depth for the large magnitude 2011 Tohoku events (test events A and E). Refer to Figures S5, S6,S7 and S8 for the flood prediction and evaluation metrics.

There is high accuracy in mapping of the flood area, but there is a tendency to misrepresent the flood depths in the prediction by the onshore model for the test events. We examine this misfit by plotting the accuracy score (A) for flood mapping and goodness of fit (G) for the different depth classes 0.1–1 m, 1– 2 m, 2– 5 m, 5–10 m, 10–15 m for test events in section 2.1.3 individually and events in 2.1.2 lumped together at the three test sites as shown in Figures 16a and 16b.

To provide an overview of the surrogate model’s behaviour, we conducted a comparative analysis between the mean prediction of the test events from the Design of Experiments (DOE) and historical events. In Fig.17a, we plot the prediction performance, assessed by G, with the magnitude of the event represented by the L2Norm. Our analysis reveals a degradation in G values for events with L2Norm values below 10. This trend can be attributed to the optimisation process driven by the
use of MSE as the loss function, which tends to prioritise accuracy for larger values. Furthermore, in Fig.17b, we compare the coefficient of determination between predictions and true observations against G as a metric for prediction performance. This visualisation effectively identifies areas where the model performs exceptionally well, but also highlights events where low G value can have a poor COD value due to poor prediction for a portion of the time series, as seen for test event A for Rikuzentakata, or over prediction as seen for the maximum inundation depths for event B in Rikuzentakata.

5 Discussion and conclusions

The general challenge with the use of such neural network surrogates for use in PTHA is that they have not been comprehensively validated if they generalise well beyond the specific type of events on which they are trained, such as events with...
different source mechanisms or when considering tsunami generated from multiple source regions for PTHA. Further, the size of training sets needed are usually in the order of thousands of events for a given single source region. The emphasis is on accurate predictions for larger magnitudes, which is crucial for early warning purposes. However, for the surrogate to serve as an effective hazard approximation in Probabilistic Tsunami Hazard Assessment (PTHA), it must accurately represent both large and small magnitude events despite limited training data.

In the study we extend upon previous work and discuss the steps related to data preparation, model architecture, and model training which can help in overcoming the above stated limitations. We train and test our surrogates using a synthetic tsunami dataset modelled using rupture events of two types: Type A events with rectangular faults of uniform slip, and Type B events where a combination of multiple sub faults of different slip occur together. The surrogate was also tested for historical events modelled with different rupture models and source locations to understand their effectiveness in a general setting and the influence of such uncertainty in the initial displacement on the prediction.

To enhance prediction information, we implemented a hybrid ensemble approach that uses multiple variational models. This approach incorporates sensitivity from different training data subsets and stochastic parameter optimisations inherent in machine learning, enabling effective prediction capability. The effectiveness of surrogate models depends on the tuning of latent variables, which vary on the type of prediction parameter, size of output and complexity of the region. Our analysis suggests that more latent variables are necessary for the nearshore surrogate compared to the onshore surrogate i.e., more information needs to be compressed for time series prediction than inundation. Also, the complexity of the region has more influence than the size of the prediction locations. Cross-validation testing confirms the robustness of our surrogate models, demonstrating high accuracy and reasonably low approximation errors. This confirms the feasibility of using such surrogates in hazard assessment tasks, providing reliable predictions for time history of water levels nearshore and maximum inundation depths onshore.

The surrogate models exhibit excellent performance in predicting time series data, effectively characterising waveforms for different locations. Despite the peculiar source characteristics and input time series compared to the training dataset, the models accurately capture temporal dynamics of the events. However, high-frequency characteristics are not captured for some test events, which can be due to the choice of shallow or low number of convolution layers and limited information in the training dataset. There are also certain portions with misrepresented phases which could be due to not including the local deformation explicitly in the learning framework but instead as a pre-processing step.

Inundation prediction poses greater challenges due to the large number of locations and asymmetry in flood occurrence across the prediction locations resulting in artefact or disconnected flooding points and under-prediction in depth in the generalisation testing. Unlike time series prediction with fixed time steps, inundation prediction requires mapping to the large number of predicted locations (ranging from 6648 to 129941) tested in the study. Addressing these challenges requires further optimisation and refinement of the model architecture, which will be investigated in future studies.

While the artefact flooding can be removed with simple postprocessing routines, there is significant potential for further improvement in the onshore decoder. We set the grid resolution in our inundation simulation at 50 m due to our computational constraints, using a higher resolution around 5-10 m would mean significantly more points. Implementing multi-head encoders...
for prediction will provide more efficient and accurate predictions. Other architectural improvements and training methods when using imbalanced datasets, such as weighted sampling, up-sampling of data, and curriculum learning can also be investigated. A customised loss function balancing predictions across small and large values by weighting could further enhance model performance and address discrepancies observed in inundation prediction.

Above a certain threshold with L2Norm greater than 10, our surrogate model demonstrates stable performance, effectively predicting both small and large events (see Figures 17a). For events smaller than this threshold, we still observe good results as seen with the Tokachi earthquake whose earthquake source was outside the events used in training. This highlights the versatility of surrogate models in the prediction of events with different magnitudes and characteristics. Although our training data did not consider outer rise mechanisms, the model generalises well as also seen with the 1933 Sanriku Tsunami. This underscores the promise of further improving the method by incorporating a broader range of training data and using better source modelling techniques, as done by (Liu et al., 2021; Núñez et al., 2022). Our analyses show that the nearshore model outperforms the onshore model in terms of generalisation for the historical events.

To improve our understanding of machine learning models in tsunami prediction, further efforts are needed in acquiring more extensive training and testing datasets, conducting benchmarking and comparison studies with other surrogates or test regions and making them available open source. In summary, our study demonstrates the potential of surrogate models in accurately predicting tsunami hazard variables, while also highlighting areas for further refinement to improve model performance and reliability in hazard assessment tasks.

Understanding the impact of the size of the training dataset and the variability it contains is important and should be examined. Topography and coastal morphology, the number of model inputs, type of prediction, and the tsunami sources considered among other factors, all contribute to the size of data needed for training and the resulting surrogate prediction performance.

While the computational time in training a machine learning surrogate is only minutes, see Table S6, we should also consider the multiple runs needed for testing and fine-tuning the model architecture, hyperparameters and other choices at hand for the ML model. Standardising the model architecture and procedures along with the use of pre-trained models for transfer learning can help minimise these training related costs.

The nearshore approximation approach is useful as a dynamic hazard proxy at the coast where considering the arrival time of tsunami and its peaks is important for studying applications such as evacuation planning. However, the direct application may be limited by the need to train the model for each location. This may hinder the application at scale, but the option to predict the inundation maps helps to efficiently assess large regions. Our approach can help extend offshore tsunami hazard information (Davies et al., 2018; Basili et al., 2021) available at deep offshore points to the much-needed onshore hazard and risk, with a relatively limited number of simulations and associated computational costs. The learning from this study can easily be adapted for other intensity measures or parameters like velocity or momentum flux, but also find use in early warning settings where direct tsunami sensors are not yet available. Similar computational challenges also exist for other coastal flood hazards like storm surge, coastal flooding due to riverine, tropical cyclone rainfall and compound flood drivers, and use of such surrogate can also be investigated in these cases using different set of input parameters.
Code availability. The tsunami simulations use GeoClaw. Pytorch was used as the machine learning framework in python, other analysis was conducted using bespoke scripts in python, maps were prepared using Pygmt package in python and QGIS. All scripts and codes used in the project and those for the preparation of the paper are available at https://github.com/naveenragur/tsunami-surrogates.git.

Data availability. The Japan Cabinet Office Data from the modelling study by special Investigation Committee on Subduction-type Earthquakes around the Japan Trench and Chishima Trench (Central Disaster Prevention Council) are publicly available at https://www.geospatial.jp/ckan/organization/naikakufu-002. The COP-DEM (https://doi.org/10.5069/G9028PQB) are available through OpenTopography from https://portal.opentopography.org/raster?opentopoID=OTSDEM.032021.4326.3. The observed water level, astronomical tide level, and tidal level deviation observed from the 2011 off the Pacific coast of Tohoku earthquake tsunami is publicly available from NOWPHAS at https://nowphas.mlit.go.jp/pastdata. The 2011 off the Pacific coast of Tohoku earthquake tsunami information - field survey results used for the validation of the GeoClaw model are publicly available from the Coastal Engineering Committee of the Japan Society of Civil Engineers website at https://www.coastal.jp/tsunami2011. The fault parameters used to model the initial displacement for the historic events are publicly available at the links cited in the references. Large input files for GeoClaw and their post-processed outputs used to train and test the surrogate models are available at https://doi.org/10.5281/zenodo.10817116.

Author contributions. N.R.R., K.J., M.P. and M.M conceived and designed the research. N.R.R conceived the experiments, carried out the simulation, developed the machine learning model and performed the training. All authors analysed, reviewed the results and wrote the manuscript.
