18 **Abstract**

19 The Northwestern Yunnan Region (~~NWYR~~), located on the southeastern edge of the
20 Tibetan Plateau, is characterized by a combination of ~~low-crustal flow~~ductile flow of
21 the lower crust with low shear-wave velocity –and gravitational collapse, giving rise
22 to a complex network of active faults. This presents significant seismic hazards,
23 particularly due to the potential for multi-segment ruptures and resulting landslides,~~as~~
24 ~~demonstrated by the historical 1515 M7.8 Yongshen Earthquake~~. This article presents

25 ~~ed a new novel~~ seismic hazard modeling ~~study~~ for the Northwestern Yunnan
26 Region~~NWYR~~, ~~incorporating recent findings on fault geometry and slip rates~~
27 ~~along integrating fault slip parameters with historical seismicity rates to~~ and assessing
28 multi-segment rupturing risks. Among the four potential multi-segment rupture
29 combination models examined, Model 1, characterized by multi-segment rupture
30 combinations on ~~singlesingle~~ faults, particularly fracturing the Zhongdian fault, ~~is~~
31 ~~proposed as~~~~emerges as~~ the most suitable for the Northwestern Yunnan Region~~NWYR~~,
32 ~~given that the non-mainshock slip (NMS) ratios on fault segments are all below the~~
33 ~~30%~40% threshold, as supported by the alignment agreement of modeled seismicity~~
34 rates with fault slip rates. Our analysis ~~demonstrates demonstrates shows~~ ~~that~~ ~~the Peak~~
35 ~~Ground-motion Acceleration (peak ground motion acceleration (PGA))~~ values ~~for a~~
36 ~~mean return period, calculated with of a~~ 475 ~~years, which is calculated with the~~
37 ~~developed probabilistic seismic hazard model, return period from modeled seismicity~~
38 ~~rates, exhibited~~ has a strong correlation with ~~the spatial distribution of the faults. Ofault~~
39 ~~distribution, on average, these values are~~ higher than ~~the the~~ ~~PGA~~ ~~ase given provided~~
40 ~~by the~~ China Seismic Ground Motion Parameters Zonation Map. ~~Furthermore, we~~
41 ~~utilized PGA values with the Bayesian Probability Method and a Machine Learning~~
42 ~~Model to predict landslide occurrence probabilities, as a function of~~ ~~based on~~ our PGA
43 ~~distribution map~~ ~~we conducted simulations to forecast landslide occurrence~~
44 ~~probabilities across our peak ground motion acceleration distribution map.~~ Our
45 findings underscored that the observed combinations of multi-segment ruptures and
46 their associated behaviors were in alignment with the small block rotation triggered by

55

56

57 **1. Introduction**

58 The collision of the Eurasian Plate and the Indian plate makes the Tibetan Plateau, the
59 world's highest, with altitude of 4000+ m averagely. The eastern extrusion of the crust
60 in the Tibetan Plateau, associated with the wedged Eastern Himalayan syntaxis,
61 initiates a clockwise rotation of crustal deformation in the southeastern margin of the
62 Tibetan Plateau (Figure 1) (Zhang et al., 2004; Gan et al., 2007; Wang and Shen, 2020).

63 The Northwestern Yunnan Region (NWYR), in the west part of the southeastern margin
64 of the Tibetan Plateau, borders the Tibetan Plateau, with the Lijiang-Xiaojiang fault
65 serving as a boundary fault. This fault ~~that~~ separates the Tibetan Plateau, boasting an
66 average altitude of over 3000 meters, from the Yunnan Region, which maintains an
67 average altitude of over 2000 meters (Yu et al., 2022; Zhang et al., 2022) (see Figure
68 1). Unlike the thrust faults along ~~in~~ the plateau boundary, such as the Longmenshan fault

69 ruptured by the 2008 M_w 7.9 Wenchuan earthquake, the Holocene slip type of the
70 Lijiang-Xiaojinhe fault is sinistral, with a strike-slip rate of ~~approximately ~~~ 3 mm/yr,
71 ~~as determined by~~ from geological (Xu et al., 2003; Shen et al., 2005; Ding et al., 2018;
72 Gao et al., 2019) and geodetic data (Gan et al., 2007; Cheng et al., 2012).

73 The peculiar slip behavior of the Lijiang-Xiaojinhe fault has garnered considerable
74 attention in studies pertaining to crustal structure, fault activities, and earthquake
75 hazards (Xu et al., 2003; Cheng et al., 2012; Zhao et al., 2013; Bao et al., 2015; Zhang
76 et al., 2020; Huang et al., 2022; Zhang et al., 2022; Dai et al., 2023). Zhang et al. (2020)
77 ~~employed~~ a shear-wave velocity model ~~was employed~~ to reveal that three faults—the
78 Longmenshan fault, the Lijiang-Xiaojinhe fault, and the Chenghai fault—
79 ~~outlined~~ delineate a low-velocity belt in the lower crust. This investigation
80 ~~uncovered~~ veiled the presence of low-crustal flow beneath the ~~Northwestern Yunnan~~
81 ~~Region~~ (NWYR). Similarly, Zhang et al. (2022) utilized magnetotelluric (MT)
82 observations in the southern vicinity of the Lijiang-Xiaojinhe fault, corroborating these
83 findings and ~~emphasizing~~ highlighting the NWYR as a pathway conduit for ductile low-
84 crustal flow in 10 km depth. Analogously, a GPS study by Cheng et al. (2012) yielded
85 comparable results.

86 Upon ~~eliminating~~ removing the rigid rotation component from the regional GPS
87 velocity field, they demonstrated a clockwise rotation ~~propelled~~ driven by ductile
88 crustal flow, particularly accelerated within the NWYR. They posited that this
89 acceleration in clockwise rotation might also be intensified by the tensional drag
90 originating from the Burma Plate. _

91 The intricate network of crustal deformation encompassing the ~~Northwestern Yunnan~~
92 ~~Region (NWYR)~~ introduces complexity to the slip behavior of faults ~~and the focal~~
93 ~~mechanisms of recent earthquakes~~. Within this area, three distinct fault slip behaviors
94 are observed: the NE-trending Lijiang-Xiaojinhe fault displays left-lateral strike-slip,
95 NW-trending faults exhibit right-lateral strike-slip, and North-South trending faults
96 demonstrate normal slip (see Figure 2). The presence of faults with diverse rupture
97 behaviors ~~contribute~~contributes to the complexity of earthquake hazards. Historically,
98 these faults have been associated with significant seismic events and numerous
99 casualties. Notably, three earthquakes with $M7+$ ~~have~~ occurred in the NWYR: the
100 Yongsheng earthquake of 1515 ($\sim M7.5$) on the Chenghai fault, the Midu earthquake of
101 1652 ($\sim M7$) on the Red River fault, and the Dali earthquake of 1925 ($\sim M7$) on the
102 Diancangshan East fault. Additionally, the 1990 Lijiang earthquake ($M_S7.0/M_W6.6$)
103 occurred on the Yulong East fault, exhibiting dominant normal slip behavior. Historical
104 and paleo-earthquake studies suggest that nearly all of these faults have the potential to
105 generate catastrophic earthquakes (e.g., Ding et al., 2018; Ren et al., 2007; Chang et al.,
106 2014), and induced numerous landslides (Institute of Geology-State Seismological
107 Bureau, and Yunnan Seismological Bureau, 1990; Huang et al. 2021).

108 Fieldwork studies and focal mechanisms of recent earthquakes underscore the
109 complexity of fault slip behaviors in this tectonic environment (Figure 2). Both
110 historical and instrumental earthquakes have affected nearly all faults in the region,
111 emphasizing the seismic risks in NWYR. For instance, the 2013 Deqin earthquake
112 swarm, reaching a maximum magnitude of $M_S5.9/M_W5.7$ on August 31 (Wu et al.,

113 2015), and the 2021 Yangbi earthquake swarm, reaching a maximum magnitude of
114 $M_s5.9/M_w6.1$ on May 21 (Zhou et al., 2022), are noteworthy seismic events (Figure 2).
115 The 2013 $M_w5.7$ Deqin earthquake swarm, characterized by tensional stress, occurred
116 at the intersection of the Zhongdian fault and the southern part of the Jinshajiang fault,
117 illustrating the susceptibility of the regional stress field to disturbance. Conversely, the
118 2021 $M_w6.1$ Yangbi earthquake swarm occurred at the connection point of the dominant
119 dextral strike-slip faults, namely the Red River fault and the Weiqi-Qiaohou fault,
120 representing a different tectonic environment compared to the 2013 $M_w5.7$ Deqin
121 earthquake swarm. This distinct setting suggests that either of these two faults could
122 may be at risk of seismic activity during the pre-earthquake period of the upcoming
123 earthquakes in this region.
124 ~~Due to the~~ The high altitude, dense vegetation, and easily weathered conditions make it
125 challenging to obtaining accurate fault slip rates ~~poses a significant challenge~~, often
126 ~~resulting in significant errors.~~ resulting in significant errors. However, recent studies
127 have provided fresh insights into slip rates and fault behaviors, offering the potential to
128 enhance the precision of seismic hazard models. For instance, ~~determining the dextral~~
129 ~~slip rate of the Zhongdian fault has proven particularly difficult due to high error~~
130 ~~margins.~~ Wu et al. (2019) Recent research has evaluated the Holocene dextral slip rate
131 of the Zhongdian fault to be $\sim 1.5 \pm 0.2$ mm/yr based on displacements of water-ice
132 remains ~~(Wu et al., 2019)~~, while Chang et al. (2014) obtained ~~and~~ $\sim 2.1 \pm 0.2$ mm/yr
133 based on displacements of river terraces ~~(Chang et al., 2014)~~, both utilizing Optically
134 Stimulated Luminescence (OSL) dating. These values notably differ from the right-

135 lateral slip rate of 4--6 mm/yr estimated by Shen et al. (2001) based on gully
136 displacements from the last glacial period, but are more aligned with the rates derived
137 from GPS velocity data (Cheng et al., 2012). Incorporating these updated fault slip rates
138 into regional seismic hazard models has the potential to greatly improve ~~holds the~~
139 ~~promise of enhancing~~ their accuracy and. ~~Therefore, integrating these new slip rates~~
140 ~~into the regional seismic hazard model is crucial to~~ ensure the reliability of the results.

141 -

142 Given the inherent challenges of fieldwork studies on fault activities, only a limited
143 number of investigations have been conducted regarding seismic hazard analysis in the
144 ~~Northwest Yunnan region~~ NWYR. Among these studies, Zhou et al. (2004) conducted a
145 micro-zonation of seismic hazards in the NWYR. They examined regional fault
146 activities through field surveys and estimated the potential maximum magnitude of
147 these faults. Their approach involved outlining polygons around the source faults to
148 divide them into different potential seismic sources and calculating historical seismicity
149 rates within these polygons. This methodology is widely employed in seismic hazard
150 modeling in China, particularly in the national seismic hazard map of the China Seismic
151 Ground Motion Parameters Zonation Map (CSGMPZM) (Gao et al., 2015). The
152 CSGMPZM also utilized this methodology to assess potential maximum magnitudes
153 and compute seismicity rates. However, their studies often did not integrate fault
154 geometry models, especially fault segmentation ~~models~~ data. Consequently, the fault
155 geometry, including rupture length and area, may not be accurately linked to the
156 magnitude of large earthquakes. Furthermore, it is crucial to recognize the potential

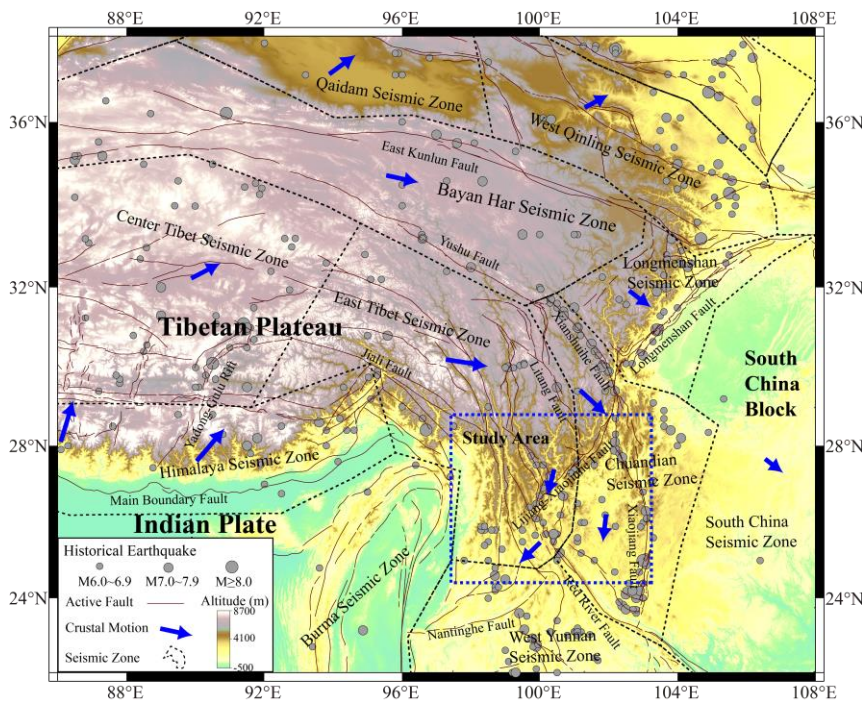

157 occurrence of multi-segment rupturing, which has not been documented in historical
158 records. Similarly, seismicity rates were typically derived solely from historical
159 earthquakes and were not synchronized with fault slip rates. Relying solely on historical
160 earthquakes for seismicity rate calculations may lead to either overestimation or
161 underestimation of seismic hazards.

162

163 In this article, we developed a regional seismic hazard model for the [Northwestern](#)
164 [Yunnan Region \(NWYR\)](#), accounting for fault slip behaviors, the potential ~~occurrence~~
165 ~~offor~~ large earthquakes, ~~and including~~ the likelihood of multi-segment ruptures. We
166 initially developed fault segmentation models for the primary active faults in the
167 [Northwestern Yunnan Region \(NWYR\)](#), drawing on recent geological research on fault
168 segmentation and geological fault slip rates. Subsequently, we employed the SHERIFS
169 code (Chartier et al., 2017; 2019) to simulate seismicity rates across possible multi-
170 segment combination models. We identified the multi-segment combination model that
171 best aligns with the majority of fault slip rates, considering fault segmentation and
172 historical seismicity rates. ~~Ultimately, we calculated the Peak Ground Acceleration~~
173 ~~(PGA) with a 10% probability of exceedance within 50 years using the seismicity rates~~
174 ~~from the selected fault segmentation models. Ultimately, we calculated the Peak~~
175 ~~Ground Acceleration (PGA) with a 10% probability of exceedance within 50 years~~
176 ~~using the seismicity rates from the selected fault segmentation models and the logic tree~~
177 ~~model of GMPEs analyzed to be suitable for China mainland.~~ The exploration of multi-
178 segment rupture combinations, along with the resultant modeled seismicity rates and

179 PGA values, offers valuable insights into the seismic hazard present in the NWYR. By
 180 leveraging the modeled PGA values and accounting for the site response of different
 181 rock type, we employed a machine learning model to compute the probability
 182 distribution of landslides induced by potential seismic hazards. This increasinged
 183 precision and reliability will be invaluable for guiding disaster preparedness initiatives,
 184 land-use planning, and infrastructure resilience strategies in the area.

185
 186

 191

207 2. Fault slip rates, Segmentation, and Multi-segment Rupture Combinations

208 Models

209 2.1 Fault slip rates, Segmentation

Formatted: Heading 2, None, Line spacing: single

210 In the NWYR, the Lijiang-Xiaojinhe fault, characterized by its left-lateral strike-slip
211 rate, and the northern ~~sectionsegment~~ of the Red River fault, ~~which displaysknown for~~
212 ~~its~~ significant right-lateral strike-slip movement, play pivotal roles in crustal
213 deformation. ~~Moreover, as a result of t~~While the southward crustal extrusion of the
214 Tibetan Plateau enhances the left-lateral strike-slip of the NE-trending faults
215 ~~likesuch as~~ the Lijiang-Xiaojinhe fault ~~also manifest a left lateral strike slip component.~~
216 These observations underscore the complex interplay of fault dynamics in the NWYR,
217 as elucidated by previous studies (Gan et al., 2007; Cheng et al., 2012; Wang and Shen,
218 2020).

219 To counterbalance the southwestward crustal extrusion (Wang et al., 1998; Cheng et al.,
220 2012), several other faults in the region, such as the Chenghai fault, the Ninglang fault,
221 the Heqing-Eryuan fault, the Yulong East fault, and the Longpan-Qiaohou fault (also
222 known as the Jianchuan fault), also exhibit a component of normal slip rate as well
223 (Institute of Geology-State Seismological Bureau, and Yunnan Seismological Bureau,
224 1990; Han et al., 2004) ([see Figure 2](#)). In contrast, the Zhongdian fault and the northern
225 part of the Red River fault, including the Weixi-Qiaohou fault and the Diancangshan
226 East fault, exhibit right-lateral strike-slip movement (Zhou et al., 2004; Han et al., 2005).
227 Recent focal mechanisms of intermediate earthquakes indicate a complex regional

228 stress field, featuring both strike-slip and normal faulting regimes (Figure 2). Table S1
229 provides an overview of the observed fault slip rates in the NWYR.

230 The Lijiang-Xiaojinhe fault serves as a boundary fault ~~delineating~~ separating the
231 Tibetan Plateau from the Central Yunnan block (Xu et al., 2003; Cheng et al., 2012).

232 We divided the Lijiang-Xiaojinhe fault into 10 segments (the F1~F10 segments in
233 Figure 3) based on fault geometry and its intersection with other faults. For the F1
234 segment, known as the Jinpingshan fault, recent fault mapping reveals a Holocene left-
235 lateral slip rate ranging from 1.3 ~~to~~ ~2.7 mm/yr derived from gully displacement across
236 the segment, while the vertical slip rate is approximately 0.2 mm/yr (Mr. Rui Ding,
237 2024, private communication).

238 Regarding the F5~F10 segments, Gao et al. (2019) demonstrated that the Hongxing-
239 Jianshanying segment (F6 segment in Figure 3) exhibited a Holocene left-lateral slip
240 rate of 3.32 ± 0.22 mm/yr with a normal slip rate component of 0.35 ± 0.02 mm/yr,
241 whereas the Runan-Nanxi segment (F10 segment in Figure 3) had a Holocene left-
242 lateral slip rate of 2.37 ± 0.20 mm/yr. Accordingly, we applied the slip rate of the F6
243 segment ~~to~~ for the F4~F7 segments, and the slip rate of the F10 segment ~~for~~ to the
244 F8~F10 segments. Notably, we considered the strike-slip motion of the F5~F10
245 segments to originate from two sources: the strike-slip Jinpingshan fault and the strike-
246 slip of the Litang fault, aligning with the observed clockwise rotation of regional crustal
247 deformation around the Litang fault and the Lijiang-Xiaojinhe fault. Consequently, we
248 inferred the left-lateral strike-slip rate of the F4 segment to be ~ 2.1 mm/yr, consistent
249 with the southern section of the Litang fault (Zhou et al., 2007). However, the F2 and

250 F3 segments, which link the F1 and F4 segments, lack recorded fault slip rates from
251 fieldwork studies. In this regard, we assigned a conservative estimate, employing half
252 the value of the strike-slip rate of the F1 segment for both the F2 and F3 segments,
253 approximately 1.2 mm/yr.

254 For the Longpan-Qiaohou fault (comprising the F11~F14 segments), we delineated it
255 into four distinct segments based on the fault mapping data provided by Wu et al. (2023).
256 The sinistral slip rate of the Longpan-Qiaohou fault was estimated at ~2.2 mm/yr over
257 the past 3500 years, with a normal slip rate of 0.23 mm/yr (Institute of Geology-State
258 Seismological Bureau, and Yunnan Seismological Bureau, 1990).

259 As for the Yulong East fault, we ~~segmented-divided the fault~~ into two segments,
260 namely the F15 and F16 segments, utilizing fault mapping data and Quaternary
261 sedimentary distribution. The slip rate of the Yulong East fault was assessed by Han et
262 al. (2005), who determined that the Quaternary left-lateral and normal slip rates are
263 0.84 mm/yr and 0.70 mm/yr, respectively, derived from the displacement observed in a
264 gully crossing the fault.

265 Regarding the Zhongdian fault, we partitioned it into six segments, designated as the
266 F17~F22 segments, based on fault mapping data (Wu et al., 2023). The Holocene
267 dextral slip rate of the Zhongdian fault is estimated to be approximately 1.7-2.0 mm/yr,
268 with a minor normal slip rate of 0.6-0.7 mm/yr based on terrace displacement across
269 the fault (Chang et al., 2014).

270 For the Heqing-Eryuan fault, we segmented it into two sections, labeled as the F23 and

271 F24 segments. The Quaternary dextral slip rate and normal slip rate of the Heqing-
272 Eryuan fault were reported to be around 2 mm/yr and 0.7–1.0 mm/yr, respectively, as
273 documented by the Institute of Geology-State Seismological Bureau, and Yunnan
274 Seismological Bureau (1990). Additionally, recent research by Sun et al. (2017) yielded
275 similar fault slip rate results, indicating a left-lateral slip rate of 1.80 mm/yr and a
276 vertical slip rate of 0.28 mm/yr since the Pleistocene.

277 The Ninglang fault is primarily characterized as a left-lateral strike-slip fault, although
278 it exhibits a minor normal slip component of less than 0.1 mm/yr at the basin margin.
279 The strike-slip rate of the Ninglang fault, as determined from fault mapping work
280 conducted by Dr. Panxing Yang from Institute of Earthquake Forecasting, China
281 Earthquake Administration (2024, private communication), was estimated to be less
282 than 1 mm/yr. For our analysis, we opted to utilize a median value of 0.5 ± 0.4 mm/yr
283 for the strike-slip rate of the Ninglang fault. Based on the distribution of Quaternary
284 sediments, we divided the Ninglang fault into two distinct segments, designated as the
285 F25 and F26 segments.

286 ~~For the Chenghai fault, t~~The sinistral slip rate of the Chenghai fault has been estimated
287 ~~to range from~~ 2.5 to 3.0 mm/yr, determined from the erosion rate of the Jinshajiang
288 River crossing the fault. Additionally, the normal slip rate is reported to be ~~~ between~~
289 ~~0.7–and~~ 1.0 mm/yr, assessed from the lift rate of the fault scarps (Institute of Geology-
290 State Seismological Bureau, and Yunnan Seismological Bureau, 1990), ~~which is~~
291 consistent with the findings of Tang et al. (2017). We divided the Chenghai fault into
292 three segments, i.e., the Chenghai segment (the F27 segment), the Qina segment (the

293 F28 segment), and the Bingchuan segment (the F29 segment), based on the sedimentary
294 distribution (Huang et al., 2018; Yu et al., 2005).

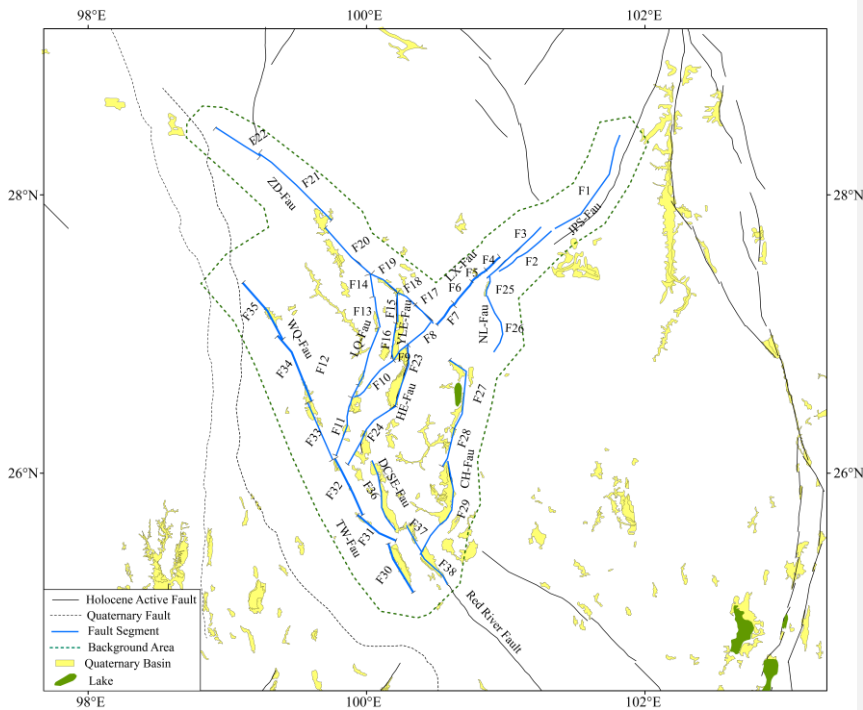

295 The southern end of the Longpan-Qiaohou fault separates the Weixi-Qiaohou fault from
296 the Tongdian-Weishan fault. We segmented these two faults into six segments each
297 based on fault mapping data and Quaternary sedimentary distribution. Concerning the
298 slip rate of the Tongdian-Weishan fault, the dextral slip rate in the Late Pleistocene is
299 estimated to be $\sim 1.8\text{-}2.4$ mm/yr, with a normal slip rate of $0.17\text{-}0.35$ mm/yr, calculated
300 from the displacement of fault scarps (Chang et al., 2016).

301 In contrast, for the Weixi-Qiaohou fault, the dextral slip rate is ~ 1.25 mm/yr, while the
302 normal slip rate is ~ 0.91 mm/yr since the Late Pleistocene (Ren et al., 2007). Comparing
303 these rates to the dextral slip rate from the middle section of the Red River fault, which
304 is reported to be 1.1 ± 0.4 mm/yr (Shi et al., 2018), it is evident that the dextral slip
305 rates decrease from the northwest to the southeast across the Red River fault system,
306 encompassing the Weixi-Qiaohou fault, the Tongdian-Weishan fault, and the Red River
307 fault.

308 The Diancangshan East Fault is the seismogenic fault of the 1925 $M7$ Dali earthquake.
309 We deduced that the Diancangshan East fault is a dominant normal slip fault as the
310 boundary fault of the Dali basin and the Erhai Lake. The normal slip rate of this fault is
311 $1\text{-}2$ mm/yr (Guo et al., 1984; Zhou et al., 2004).

312 Additionally, we incorporated the F37 and F38 segments of the northern part of the Red
313 River fault into our segmentation model. The right-lateral strike-slip rate of these two

314 segments is ~ 1.1 mm/yr. Figure 3 illustrated the segmentation model of the faults in the
315 NWYR.

316
317 Figure 3. Fault segmentation model for the **Northwestern Yunnan Region (NWYR)**.

318 In which, the Quaternary Basin distribution were from Deng et al. (2003); the fault
319 data are from Wu et al. (2023).

320

321 2.2 Multi-segment Rupture Combinations Models

322 Recently, geological and geophysical studies have documented several large
323 earthquakes characterized by multi-segment rupturing. Notable examples include the
324 M_w 7.4 Landers earthquake in 1992 (Campillo and Archuleta, 1993), the M_w 7.9
325 Wenchuan earthquake in 2008 (Xu et al., 2009), the M_w 7.8 Kaikoura earthquake in

Formatted: Heading 2, Line spacing: single

326 2016 (Xu et al., 2018), and the 2023 doublet events of M_w 7.8 and M_w 7.5 in Turkey
327 (Petersen et al., 2023). These events exhibited rupturing across different segments,
328 resulting in larger magnitudes than would be expected from single-segment ruptures.

329 Numerous studies have focused on understanding the fault's geometric and
330 physical parameters to ascertain conditions conducive to multi-segment rupturing.
331 Factors identified include step width (e.g., < 5 km) (Harris and Day, 1999; Lozos et al.,
332 2012), fault structural maturity characterized by initiation age, net slip, length, and slip
333 rate (Manighetti et al., 2007; 2021), and geometric irregularities such as fault branches
334 and bends, significantly influenced by the pre-existing stress field (Mignan et al.,
335 2015).~~For the strike-slip faults, we employed the conclusions of the step width of 5+~~
336 ~~km from dynamic rupture modelling (Harris and Day, 1999) and strike difference of 28°~~
337 ~~+ observed from fieldworks of historical rupture events (Biasi and Wesnousky, 2017)~~
338 ~~can stop the earthquake rupture to select the multi-segment rupture combinations.~~

339
340 For strike-slip faults, we applied conclusions from dynamic rupture modeling,
341 indicating that a step width of more than 5 km (Harris and Day, 1999), and a strike
342 difference of more than 28°, as observed in field studies of historical rupture events
343 (Biasi and Wesnousky, 2017), could inhibit earthquake rupture, to select the multi-
344 segment rupture combinations.

345 In our segmentation model of the NWYR, the distance of the F3 segment and the
346 F1-F2 segments is ~7 km, while the width of step between the F20 and F21 segments
347 is also ~7 km. Similarly, the distance between the F3 segment and the F4 segment is
348 ~6.5 km. Thus, we did not consider the rupture continuities of these segments. For the
349 multi-fault rupture combinations, we can excluded almost all the multi-fault rupture
350 combinations.

Formatted: Font: (Default) Times New Roman, 小四, Font color: Black

351 In our segmentation model of the NWYR, the distance between the F3 segment
352 and the F1-F2 segments is approximately 7 km, and the step width between the F20 and
353 F21 segments is also about 7 km. Similarly, the distance between the F3 segment and
354 the F4 segment is approximately 6.5 km. Based on these distances, we did not consider
355 the rupture continuity of these segments. For multi-fault rupture combinations, the
356 strike difference was also used to assess whether multi-fault rupture could occur.
357 Consequently, we excluded nearly all the multi-fault rupture combinations, except for
358 the combination between the F10 and F11 segments, which have a strike difference of
359 about 20°.

360
361 Based on the segmentation model, fault rupture behaviors, ~~and~~ the intersections
362 among fault segments; and geometric information discussed above, we developis
363 four multi-segment rupture combination models for the fault segments in the NWYR
364 (Figure 4). The M_w 6.6 Lijiang earthquake on February 3, 1996, represents a significant
365 normal rupture event that occurred on the Yulong East fault. This earthquake stands out
366 as the most substantial seismic event in the NWYR since the 1970s, underscoring the
367 normal slip behavior of the Yulong East fault. This observation suggests potential
368 ~~effect on the multi-segment rupture~~implications for the rupture behavior of the
369 Zhongdian fault.

Formatted: Indent: First line: 1 ch, No widow/orphan
control

370
371 In Model 1, we exclusively examined the multi-segment rupture combinations
372 within the same faults. Specifically, for the Zhongdian fault, we ~~included~~integrated the
373 multi-segment rupturing of the F17 and F18 segments, as well as the multi-segment
374 rupturing of the F19 and F20 segments. This approach considered the normal slip
375 behavior of the Yulong East fault (F15 and F16 segments) and its potential impact on

376 Quaternary sedimentary distribution between the F18 and F19 segments of the
377 Zhongdian fault. Subsequently, in Model 2, we evaluated the plausibility of multi-
378 segment rupturing occurring across the F17~F20 segments.

379 In the NWYR, the prevailing fault behavior is sinistral slip along the northeast-
380 trending faults, a trend consistent with the observed clockwise rotation in regional
381 crustal deformation (Cheng et al., 2012) and the presence of ductile low-crust flow
382 (Zhang et al., 2022). The sinistral slip observed along the Longpan-Qiaohou fault may
383 ~~strongly impacted on~~ ~~hinder~~ the dextral slip occurring along the Weixi-Qiaohou fault,
384 which extends from the Tongdian-Weishan fault, contributing to the decrease in dextral
385 slip rates observed from the Weixi-Qiaohou fault to the Tongdian-Weishan fault. In
386 Model 3, we integrated the multi-segment rupture combination of the Weixi-Qiaohou
387 fault (the F33~F35 segments) and the Tongdian-Weishan fault (the F30~F32 segments).

388 In 2023, two earthquakes of $M_w7.8$ and $M_w7.5$ successively ruptured the East
389 Anatolia fault region in Turkey (Xu et al., 2023; Petersen et al., 2023). The rupture of
390 the first earthquake, with $M_w7.8$, initiated on the splay Narli fault and propagated
391 bilaterally along the main East Anatolia fault (Liu et al., 2023). Consequently, we took
392 into account the possibility of rupture propagation from one fault to another in our
393 rupture combinations. Using Model 4, we investigated whether the rupture on the
394 Lijiang-Xiaojinhe fault could propagate to the Longpan-Qiaohou fault. This
395 consideration was prompted by similarities in the rupture behavior between the F11
396 segment of the Longpan-Qiaohou fault and the F10 segment of the Lijiang-Xiaojinhe
397 fault (Table S1), along with a ~~minor~~ ~~strike~~ difference of $\sim 20^\circ$, ~~smaller than the threshold~~
398 ~~of 28° proposed by Biasi and Wesnousky (2017)~~ ~~in strike to prohibit the rupture~~
399 ~~process~~ (Table S1).

 401 Figure 4 Possible Rupture Combination Models for the Fault Segments in NWYR.
 402 Dashed rectangular show the rupture combinations for each Model.
 403

404 **3. Multi-segment rupture hazard Modeling**

405 **3.1 Methodology**

406 Recently, geological and geophysical studies have documented several large
 407 earthquakes characterized by multi-segment rupturing. Notable examples include the
 408 M_w7.4 Landers earthquake in 1992 (Campillo and Archuleta, 1993), the M_w7.9

Formatted: Font: (Default) Times New Roman, 小四, Font color: Black

409 Wenchuan earthquake in 2008 (Xu et al., 2009), the M_w 7.8 Kaikoura earthquake in
410 2016 (Xu et al., 2018), and the 2023 doublet events of M_w 7.8 and M_w 7.5 in Turkey
411 (Petersen et al., 2023). These seismic events exhibited rupturing across different
412 segments, enhancing their overall magnitude and impact.

413 Numerous studies have focused on understanding the fault's geometric and
414 physical parameters to ascertain conditions conducive to multi-segment rupturing.
415 Factors identified include step width (e.g., < 5 km) (Harris and Day, 1999; Lozos et al.,
416 2012), fault structural maturity characterized by initiation age, net slip, length, and slip
417 rate (Manighetti et al., 2007; 2021), and geometric irregularities such as fault branches
418 and bends, significantly influenced by the pre-existing stress field (Kame et al., 2003;
419 Mignan et al., 2015).

420 Recognizing the importance of these rupture parameters in producing multi-
421 segment rupturing, recent studies, such as those by Chartier et al. (2019), Cheng et al.
422 (2021), Lee et al. (2022), and Chang et al. (2023), included the possibilities and
423 probabilities of multi-segment rupturing in seismic hazard analysis. Additionally,
424 Dutykh et al. (2013) and Rashidi et al. (2020) employed multi-segment rupturing into
425 models of tsunami wave generation. The concept of multi-segment rupturing was also
426 incorporated in the UCERF3 model through their complex "Grand Inversion"
427 methodology, which integrates data on fault slip rates, historical seismicity, and paleo-
428 earthquake records (Page et al., 2014; Field et al., 2014). However, for most other
429 regional studies, collecting all the necessary input parameters remains challenging.

430 In seismic hazard modeling, fault slip rates can be used instead of historical
431 seismicity data to simulate seismicity rates on faults, as slip rates span multiple seismic
432 cycles of large-magnitude earthquakes and provide estimates of the average earthquake
433 recurrence interval (Youngs and Coppersmith, 1985). W

434 ~~Here, w~~We utilized the methodology developed by Chartier et al. (2019) to
435 translate these fault slip rates into seismicity rates, considering both multi-segment and
436 single-segment ruptures.

438 3.1 Methodology

439 In ~~the~~ our earthquake hazard modeling, the seismicity rates should reflect both the
440 fault slip rate and the regional magnitude-frequency distribution (MFD), e.g., the
441 Gutenberg-Richter (G-R) Relationship (Gutenberg and Richter, 1944) and the
442 Characteristic earthquake model (Schwartz and Coppersmith, 1984). Youngs and
443 Coppersmith (1995) balanced fault slip rates with ~~magnitude frequency~~
444 ~~relationship~~MFD to determine the seismicity rate on faults. They employed the
445 composite characteristic earthquake model (Y-C) or truncated G-R model to convert the
446 fault slip rate into the seismicity rates on the fault. These converted MFD were widely
447 used in seismic hazard analysis (e.g., Avital et al., 2018; Chartier et al., 2019; Rong et
448 al., 2020). This approach enables a more comprehensive assessment of earthquake
449 hazards by integrating both fault slip rates and the frequency of seismic events. For
450 assessing the possibilities and probabilities of multi-segment rupturing, it is essential to
451 represent the seismicity rate of such combinations within the magnitude-frequency
452 relationship for each segment.

453 To achieve this, Chartier et al. (2017; 2019; 2021) devised a Python-based code
454 known as SHERIFS. This code employed an iterative process, enabling the balancing
455 of occurrence rates for multi-segment rupturing events alongside intermediate and
456 small earthquakes on each fault segment (Figure 5a).

457 Leveraging historical seismicity data, they utilized the slip rate of each fault

458 segment to convert it into the target MFD on the fault, such as the G-R, or the Y-C
459 distribution. This method offered a robust framework for assessing seismic hazard,
460 integrating both single and multi-segment rupture scenarios effectively. Determining
461 the maximum magnitudes of individual fault segments and their combinations could
462 rely on fault length, following rupture scaling laws proposed by researchers (e.g., Wells
463 and Coppersmith, 1994; Leonard et al., 2010; Cheng et al., 2020). ~~Since Most of the~~
464 ~~rupture scaling relationships are for Plate boundary regions and~~

465 ~~Here, we selected the most~~ rupture scaling relationships are developed for plate
466 boundary regions (Stirling et al., 2013), we selected a regression scaling relationship
467 based on a dataset of earthquakes from China mainland (Cheng et al., 2020) and
468 compared the results with those from the widely used rupture scaling relationship by
469 Wells and Coppersmith (1994), which incorporates global data from both interplate and
470 intraplate earthquakes.

471
472 In these steps, the b -value from historical earthquakes, the rupture scaling law of
473 the faults, and the fault slip rates are typically accompanied by significant uncertainties.
474 SHERIFS used the random sampling method to explore the uncertainty bounds. For
475 every branch of the logic tree, it generates a corresponding number of models, matching
476 the total count of random samples.The rates are derived while examining uncertainties
477 related to earthquake magnitudes, the duration of the completeness period, and the
478 limited number of observed earthquakes for larger magnitudes, using a Monte Carlo
479 approach (Chartier et al., 2021). For each branch of the logic tree in the random
480 sampling, it generates a corresponding number of models that match the total count of
481 random samples. For each model, the slip-rate value is selected uniformly within its
482 uncertainty bounds, scaling law parameters are chosen independently from a Gaussian

Formatted: Font: Italic

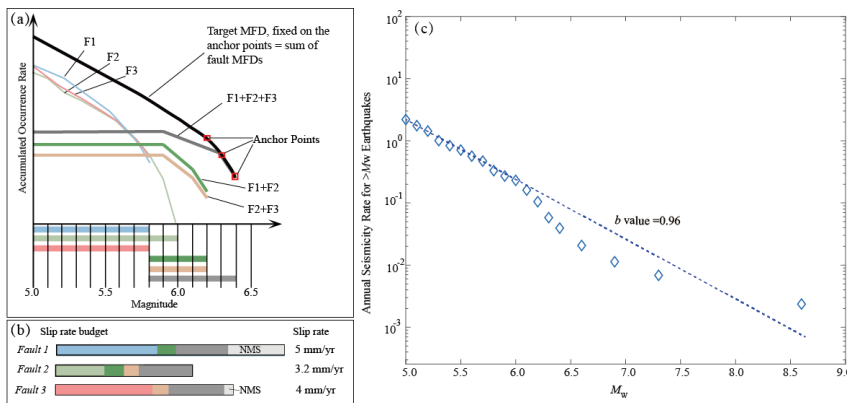

483 [distribution within their error bounds, and the \$b\$ -value is picked from the user-defined](#)
484 [range. All these uncertainties propagate to the final step of calculating seismicity rates](#)
485 [with uncertainties.](#)

487 [like Wells and Coppersmith \(1994\) and Cheng et al. \(2020\).](#)

488 In the final step, they iterated the seismicity rates across magnitude bins associated
489 with multi-segment rupturing, spanning from large magnitudes down to small
490 magnitudes, according to the target MFD for each fault segment. However, in many
491 cases, the fault slip rate or [the](#) calculated seismicity rates couldn't fully account for the
492 entire seismic activity. The remaining portion of the fault slip rate for each segment was
493 attributed to non-main-shock slip (NMS), including processes like post-seismic slip and
494 silent creep. An NMS ratio of $\leq 30\%$ ~~was~~ [40%](#) ~~i~~ [was](#) typically considered indicative of a
495 model misfit, potentially [arising from factors like ~~due to~~ creeping and specific](#)
496 [conditions, such as boundary fault segments or creeping segments \(as depicted in Figure](#)
497 [5b\).](#) Here, we adopted a similar approach in simulating seismic hazard modeling for the
498 regional fault system in the NWYR.

 505 budget of the fault slip rate and its consumption on the earthquakes (Modified from
 506 [Chartier et al., 2017](#)); c. Calculated b value for the East Tibet Seismic Zone where
 507 the NWYR located in Figure 1.

508

509 **3.2 Scaling Relationship and Modeling Parameters**

510 Given the fractured structure of the crust in the NWYR, as documented by Cao et
 511 al. (2023), the seismicity distribution in this area was notably complex and differed
 512 significantly different from that observed directly on the fault lines. Therefore, in our
 513 analysis of seismicity rates for ~~the whole seismicity rates on~~ the regional faults, we
 514 opted to utilize the ~~Gutenberg-Richter (G-R)~~ relation (Gutenberg and Richter, 1944) as
 515 the Magnitude-Frequency relationship, rather than the Youngs-Coppersmith (Y-C)
 516 relation (Youngs and Coppersmith, 1985).

517 For estimating ~~the~~ magnitudes based on rupture length, we applied the
518 ~~relationships~~ relationship proposed by Cheng et al. (2020) to determine the maximum
519 magnitude for each individual fault segment as well as their multi-segment
520 combinations. Additionally, we accounted for a portion of earthquakes with $M < 6.5$ as
521 off-fault seismicity. Specifically, we assigned probabilities of 95%, 90%, 85%, 80%,
522 and 80% for magnitude bins ~~ranging from of~~ 6.0 to 6.4, 5.5 to 5.9, 5.0 to 5.4, 4.5 to
523 4.9, and 4.0 to 4.4, respectively, based on prior studies (Chartier et al., 2019; Cheng et
524 al., 2021).

525
526 We ~~conducted a~~ calculated ~~ion of~~ the b-value for the East Tibet Seismic Zone,
527 which encompasses nearly all of the NWYR, as illustrated in Figure 1. The earthquake
528 catalog utilized for this analysis was sourced from Cheng et al. (2017), covering the
529 time period from 780 BC to 2015 AD. Additionally, we incorporated earthquakes from
530 the Global CMT catalog spanning the period from 2016 to 2023 ~~into the dataset~~.

531 The regressed b-value was approximately 0.96, with completeness times for
532 magnitudes $M_w 4.5$, $M_w 5.0$, $M_w 5.3$, $M_w 5.7$, $M_w 6.1$, and $M_w 6.4$ identified as 1985, 1966,
533 1928, 1916, 1916, and 1900, respectively. ~~It is note's worthy noting~~ that the calculated
534 ~~b~~-value is slightly higher than the value of 0.86 reported in Rong et al. (2020), likely
535 due to the inclusion of new earthquakes occurring after 2015. Figure 5e ~~provides a~~
536 ~~visualiz~~ ~~esation of~~ the Gutenberg-Richter relationship in the East Tibet Seismic Zone, in
537 which the b value is 0.96.

Formatted: Font: Italic

538 -

539

540 3.3.2 Comparison and Selection of Modeled Results

541 We depicted the NMS ratios and modeled seismicity rates in Figure 6. The right

542 panels showcased the NMS ratios of the segments in Model 1~4. Model 1 exhibited the
543 most balanced results between the modeled seismicity rates and historical ones. In
544 Figure 6a, all segments in Model 1 demonstrated NMS ratios smaller than 30%.
545 Chartier et al. (2019) suggested that NMS ratios below 30%-40% serve as a benchmark
546 to assess the validity of multi-segment combination models, indicating effective
547 consumption of the slip rate of each segment into seismicity rates ~~for each fault segment~~.
548 The left panels in Figure 6b further underscored the ~~alignment~~ harmony between the
549 modeled and observed seismicity rates. ~~Here, showing that~~ the observed historical
550 seismicity rates closely ~~aligned~~ matches with the calculated ~~rate~~ ones, particularly for
551 <M7 earthquakes.

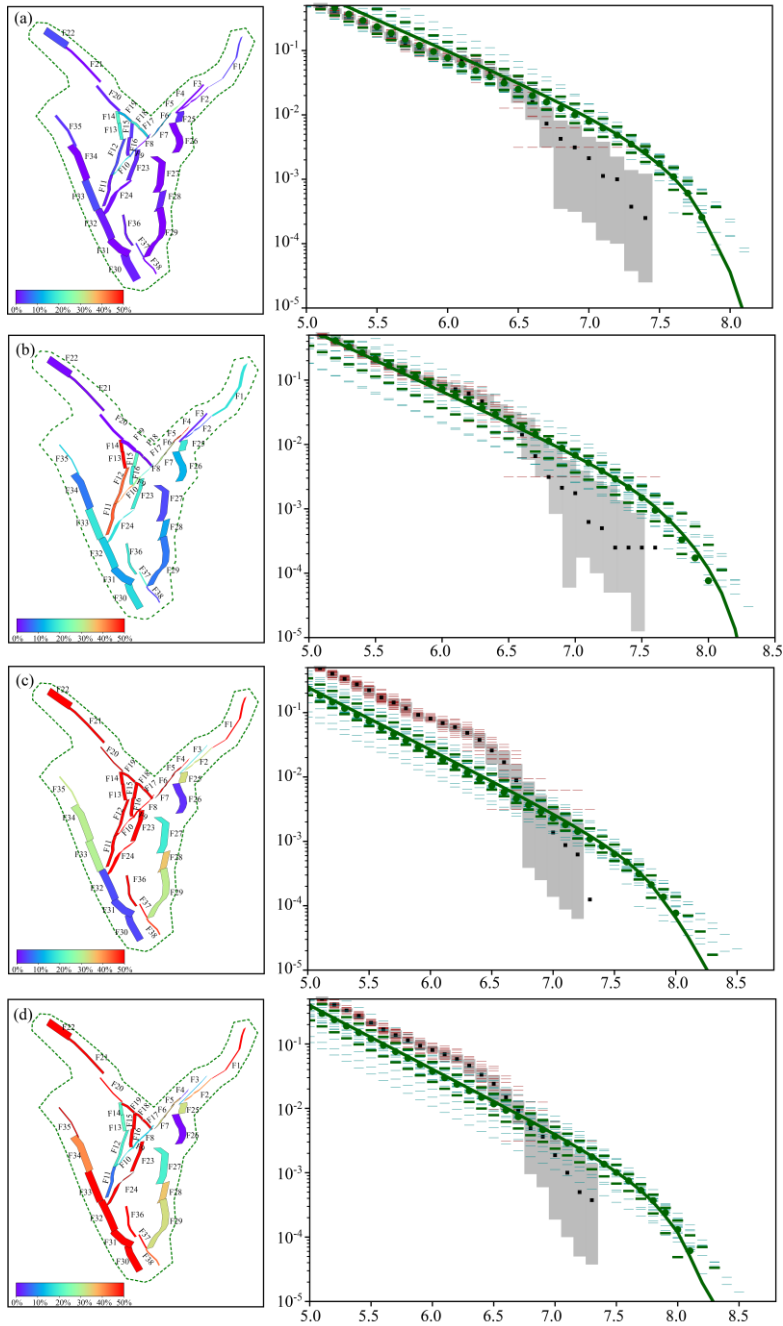

552
553 Compared to Model 1, Model 2 ~~combined~~ treats segments F17~F20 as a single
554 unit, ~~rather than separating instead of considering the~~ F17~F18 ~~segments and the~~
555 F19~F20 ~~segments separately~~. The left panel of Figure 6b indicates that the NMS ratios
556 for segments ~~of~~ F11~F14 and F4~F5 ~~are all greater than~~ exceed 40%, while the F6~F7
557 multi-segment combination has an NMS ratio ranging from 30% to 40%, showing that
558 the combination of segments F17~F20 has an obvious impact on the seismicity rates of
559 these faults. From the right panel in Figure 6b, the historical seismicity rates for each
560 fault segment were similar to those in Model 1. However, the calculated seismicity rates
561 for each segment in Model 2 ~~became smaller~~ were ~~generally lower~~ than those in Model
562 1, except for a slightly higher rate in the magnitude range of 6.0~~~6.5~~. This result
563 indicated that the fault slip rates are not being adequately accounted for in Model 2,
564 unlike in Model 1 (Figure 6a).

565
566 In Model 3, the rupture combination comprised segments of F30~F35, rather than

567 considering them separately as F30~F32 and F33~F35. Most segments exhibited high
568 NMS ratios in the left panel of Figure 6c. The calculated seismicity rates were generally
569 smaller than the historical ones in the right panel of Figure 6c. Similarly, Model 4 was
570 utilized to investigate whether the great earthquakes of the Y-shaped rupture, combining
571 segments F4~F10 with F11~F14, could occur. The NMS ratios for each segment and
572 the calculated seismicity rates were comparable to those observed in Model 3 (Figure
573 6d).

574
575 In addition, we also presented the results using the rupture scaling relationship
576 proposed by Wells and Coppersmith (1994) in Figure S1. Model 1 exhibited the most
577 consistent outcomes, with the maximum NMS ratio observed on F14 at 39.3%. The
578 NMS ratios for all other segments were below 30%. For the calculated seismicity rates
579 ~~obtained~~ from Model 2 to Model 4, using the rupture scaling relationship of Wells and
580 Coppersmith (1994), we observed similar patterns, with segments in. All three models
581 ~~exhibiting showed segments with~~ NMS ratios exceeding 40%. ~~Furthermore~~ In summary,
582 ~~we found that~~ these models, utilizing the rupture scaling of Wells and Coppersmith
583 (1994), consistently yielded higher average NMS ratios ~~on average~~ compared to those
584 obtained from the rupture scaling of Cheng et al. (2020), though the ratios were similar.

585

586
587 Figure 6 Calculated NMS ratios and comparison results for different models using the

588 G-R relation. (a) Modeled Non-Mainshock Slip (NMS) Ratio; (b) Comparisons
589 between the historical Seismicity rates for different models. Dashed green lines are the
590 MFD of each model, and the solid green line is the mean MFD, green patches represent
591 the uncertainty (16-84 percentiles). The dotted black line is the rate from the catalog;
592 the dashed red lines are individual Monte Carlo sampled rates of the catalog exploring
593 the uncertainties on the magnitudes of earthquakes, and gray rectangular show the one-
594 sigma uncertainty on the earthquake rates in statistical analysis.

Formatted: Font: (Asian) + Body Asian (等线)

596 Based on the comparison among different multi-segment rupture combination
597 models, Model 1 demonstrated the most consistent results among the multi-segment
598 rupture combinations, fault segment slip rates, and the Magnitude-Frequency
599 relationship. Therefore, we utilized the seismicity rates from Model 1 to calculate the
600 ~~Peak Ground Acceleration (PGA)~~ values for the NWYR. ~~The output of the seismicity~~
601 ~~rates consist of 20-~~

604 ~~3.43 Comparison with the results~~ Results of current Current national National 605 Seismic Hazard Map Comparison with Current National Seismic Hazard Map 606 Results

Formatted: Font: (Default) Times New Roman, 小四

607 We utilized the OpenQuake Engine v3.10 (Pagani et al., 2014) to calculate the
608 ~~Peak Ground Acceleration (PGA)~~ values for the NWYR. In this computation, we
609 employed a logic tree model comprising the Abrahamson et al. (2014); Chiou and
610 Youngs (2014); Campbell and Bozorgnia (2014); and Boore et al. (2014) branches of
611 GMPEs, along with their associated uncertainties. Each branch was assigned an equal
612 weight of 0.25, following the selection criteria established by Dangkua et al. (2018) for
613 ~~mainland~~ China Mainland. These Ground Motion Prediction Equations (GMPEs) are

614 tailored for earthquakes characterized by moment magnitude (M_w) and the distance to
615 the rupture plane (R_{rup}) or its surface projection (R_{JB}).

616

617

618

619 Figure 7a illustrates the distribution of ~~Peak Ground Acceleration (PGA) values~~
620 for the site condition of firm to hard rock ($V_{s30}=760$ m/s, or NEHRP B) resulting from
621 the seismicity ~~model rates~~ in Model 1, corresponding to a 10% probability of
622 exceedance in 50 years, ~~which is~~ equivalent to a return period of 475 years. The analysis
623 revealed concentrations of high PGA values exceeding 0.40 g near fault sources,
624 particularly in areas with multiple fault sources. These areas include the F2~F5
625 segments of the Lijiang-Xiaojinhe fault, the vicinity of the Yulong East Fault (YLE-
626 Fau), the southern part of the Zhongdian fault (ZD-Fau), and the northern extent of the
627 Heqing-Eryuan fault (HE-Fau).

628

629 The area around the F2~F5 segments includes three parallel faults, with the sum
630 of the strike-slip of ~3 mm/yr, makes the PGA values relatively higher. The maximum
631 magnitude ~~for~~ the combinations of the F17~F18 ~~segments~~ and ~~the~~ F15~F16 segments
632 are both approximately $M_w6.6$. These areas exhibit a prevalence of moderate
633 earthquakes with short recurrence intervals and high ~~Peak Ground Acceleration (PGA)~~
634 distributions over a 475-year return period. The modeled seismicity rates ~~for both~~ of the
635 F23 ~~segment~~ and the F24 segments ~~both~~ complied with the G-R relationship, ~~containing~~
636 with sufficient enough intermediate earthquakes, ~~induced~~ contributing to the high PGA
637 values in the surrounding areas around. Along the Chenghai fault, high PGA values are
638 concentrated ~~are also observed~~ around the F27~F28 segments with strike-slip rates of

Formatted: Font: Times New Roman

Formatted: Font: (Asian) +Body Asian (等线)

639 3.0 mm/yr, but are lower around the F29 segments with a strike-slip rate of 2.5 mm/yr.
640 For the Red River fault and its extensions, including the Tongdian-Weishan fault and
641 the Weixi-Qiaohou fault, high PGA values ~~are~~ were concentrated around the F37~F38
642 segments and at the intersection points of the F11, F32, and F32 segments.

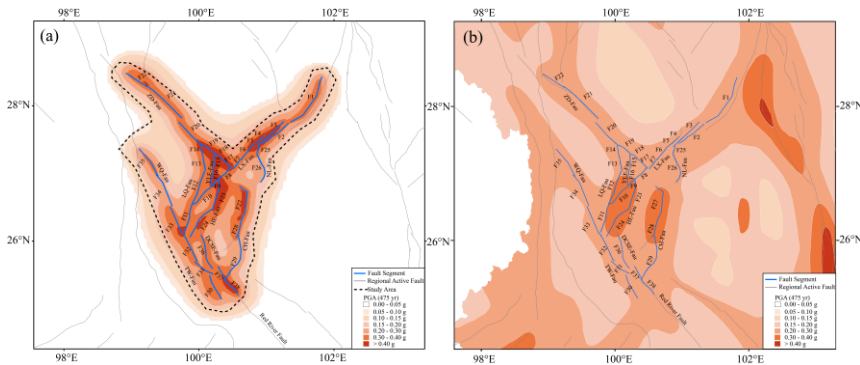

643
644 Compared ~~to~~ ison with the national seismic hazard map of the ~~China Seismic~~
645 ~~Ground Motion Parameters Zonation Map (CSGMPZM)~~ (Gao et al., 2015) (Figure 7b)
646 for the site condition of dense soil and soft rock ($V_{s30} = 500$ m/s, or NHERP C) (Chen
647 et al., 2021), our ~~Peak Ground Acceleration (PGA)~~ values are consistently ~~much~~ higher
648 and more ~~intricate~~ detailed. The V_{s30} of 500 m/s is equivalent to the Type II in the
649 classification table of CSGMPZM, while the value of 760 m/s belongs to Type I_1+ . Table
650 1 ~~presents~~ was the adjustment factors used by CSGMPZM for site amplification (Gao
651 et al., 2015). Even ~~when~~ if we applied these site amplification adjustment factors to
652 convert our PGA values from type I_1+ to type II, the PGA values would not change
653 obviously as the adjustment are ~~close~~ the near to 1 for PGA values of 0.30~0.40 g, and
654 1 for PGA values of ≥ 0.40 g. In ~~F~~ figure 7b, the CSGMPZM indicates two high PGA
655 values ranging from 0.30 to 0.40 g in the NWYR, specifically around the F23~F24
656 ~~segments~~ and the F27~F28 segments, respectively. In contrast, the PGA values in other
657 areas surrounding the fault segments in our model range from 0.20 to 0.30 g.

658 In the development of the CSGMPZM, the region in the around China was divided
659 into 29 large seismic source zones to calculate the parameters of the ~~Magnitude-~~
660 ~~Frequency Distribution (MFD)~~. Additionally, over 1,000 potential fault sources across
661 China were incorporated into the model. Historical seismicity rates on the MFD were
662 employed to predict future seismic activity. This methodology led to lower anticipated
663 seismicity rates in regions with limited historical earthquake records. The identification

Formatted: Subscript

664 of potential fault sources in the CSGMPZM relied on expert opinions gleaned from
 665 research on historical surface rupture, fault segmentation, and the distribution of past
 666 earthquakes. These data sources were subsequently utilized to allocate predicted
 667 seismicity rates based on the MFD.

668 Furthermore, the utilization of different ~~Ground Motion Prediction Equations~~
 669 ~~(GMPEs)~~ in the CSGMPZM compared to our results could also contribute to variations
 670 in PGA values. The CSGMPZM utilized GMPEs from Yu et al. (2013) based on surface
 671 magnitude (M_s) and epicentral distance (R_{epi}). Their GMPEs result in higher PGA
 672 values for distances less than 80 km but lower values for distances ≥ 80 km (Cheng et
 673 al., 2021). Consequently, the seismicity rates derived from ~~the~~ fault slip rates and ~~the~~
 674 multi-segment rupture combinations were key factors that ~~resulted in~~ ~~higher~~ our
 675 modeled PGA values higher than those from CSGMPZM.

676 Figure 7 Comparison of the Modeled PGA distribution of 10% in the next 50 years,
 677 (a) the PGA results in this article (b) the PGA results in the CSGMPZM.

Table 1 Adjustment factors for PGA values of different Site condition via Type II

PGA values for type II	Site condition type				
	I ₀	I ₁	II	III	IV
≤ 0.05 g	0.72	0.80	1.00	1.30	1.25

Formatted: Line spacing: 1.5 lines

0.10 g	0.74	0.82	1.00	1.25	1.20
0.15 g	0.75	0.83	1.00	1.15	1.10
0.20 g	0.76	0.85	1.00	1.00	1.00
0.30 g	0.85	0.95	1.00	1.00	0.95
≥0.40 g	0.90	1.00	1.00	1.00	0.90

682

683 3.5 Validity of Our the Modeled Results

684 In Figure 8, we further illustrated seismicity rates for several typical fault segments
685 to elucidate the reasons behind the observed high PGA values. ~~In~~ Figure 8a shows,
686 the seismicity rates of the F2 segment exhibit a typical G-R relationship, with a
687 sufficient number of intermediate earthquakes contributing leading to a high PGA
688 distribution in the surrounding area. We compared the seismicity rates on the F7~F8
689 segments, and the F10 segment with the recurrence intervals from paleo-earthquake
690 studies. In Figures 8b and ~8c, the red-gray bars illustrate that our modeled seismicity
691 rates align with the recurrence interval of approximately 3000 years for a *magnitude*
692 M_w 7.5 earthquake, as ~~determined-reported~~ by Ding et al. (2018).

Formatted: Subscript

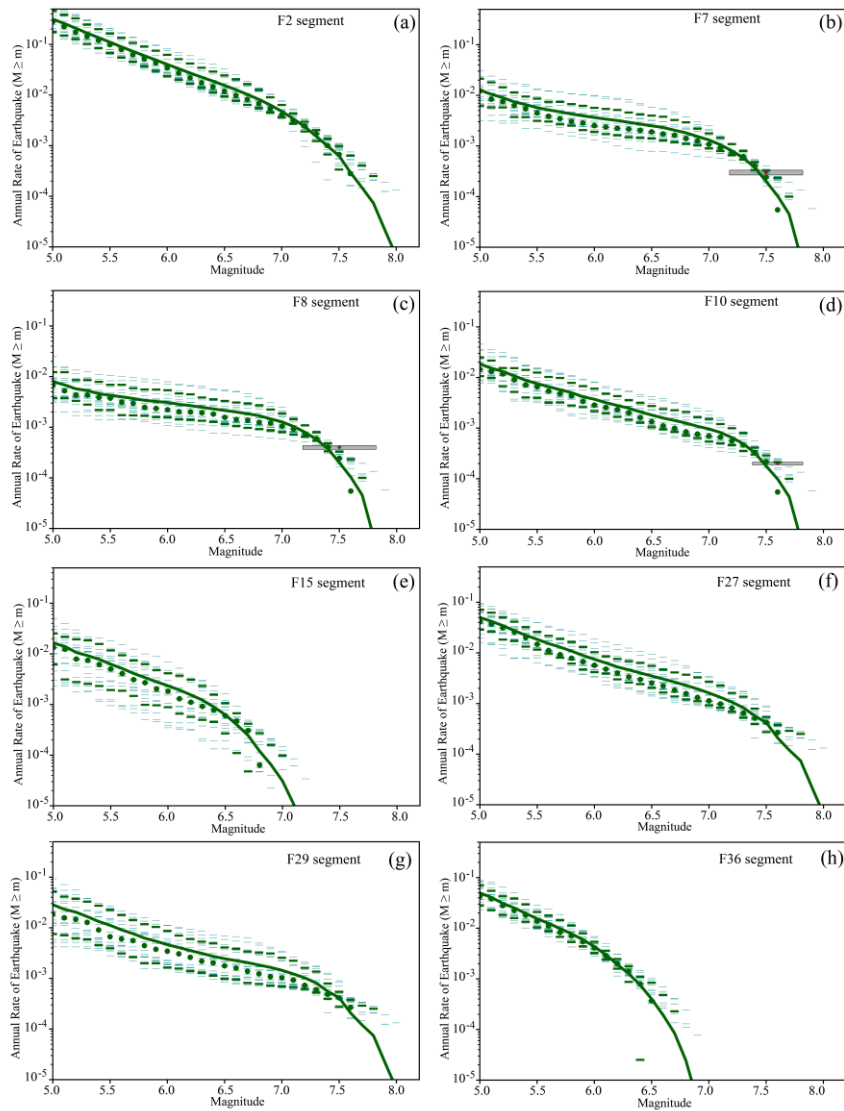

693 We ~~have~~ also observed that segments F7 to F8 of the Lijiang-Xiaojinhe fault tend
694 to ~~conform to~~ follow the characteristic earthquake model, based on their seismicity rate
695 distribution. ~~The Segment~~ F10 segment, with a length of approximately 44 km in length,
696 ~~experienced-ruptured~~ during the 1751 M 6.8 earthquake. Additionally, Tang et al. (2014)
697 identified three paleo-earthquake events with a recurrence interval of ~~around~~ ~5300
698 years for earthquakes of M 6.5+ earthquakes on the F11 segment ~~F11~~. They suggested
699 that the two paleo-events prior to the 1751 AD earthquake before 1751 AD were
700 considerably stronger ~~than the one in 1751 AD~~, implying multi-segment rupturing
701 involving combinations of segments F11+F12, F11~F13, and F11~F14 resulting in
702 magnitudes of M_w 7.4~7.6 earthquakes. Additionally, we illustrate the seismicity rates

Formatted: Font: Italic

703 ~~for~~ segments F15, F27, F29, and F36 in Figures 8e~8f, which closely ~~resemble~~
704 follow the G-R distribution, leading to high PGA distributions in their vicinity. These
705 results demonstrate that the occurrence rate of intermediate earthquakes play a
706 significant role in driving~~influences~~ the high PGA distributions.

707

708

709
 710 Figure 8 Modeled Seismicity rates for different magnitude on the fault segments. The
 711 solid line is the mean MFD, and small patches represent the uncertainty (16-84
 712 percentiles). The dotted line is the rate from the catalog with uncertainties. The red
 713 circle is the occurrence rate of the repeated large historical earthquake rate, and the gray
 714 box is the associated uncertainty.

715

716 **3.6.4 Landslide Probabilities**

717 **3.6.1 PGA Site Amplification**

718 Utilizing the modeled PGA values for rock site conditions presented in Figure 7a
719 as a foundation, we enhanced our analysis by incorporating the site amplification effects
720 derived from Chen et al.'s (2021) comprehensive site condition map. Their research,
721 leveraging geological unit data, culminated in a detailed site condition map covering
722 ~~mainland~~ China Mainland. Leveraging this invaluable resource, we integrated their site
723 condition map along with the amplification factors for each geological type compared
724 to type II (referenced in Table 1) to refine the PGA value distribution map (Figure 9a).
725 Our methodology involved multiplying the PGA values for specific site conditions by
726 the ratio of type II PGA values to those of the specific type. This approach effectively
727 ~~magnified-amplified~~ PGA values across different site conditions, ~~enhancing~~
728 granularity of our analysis. Figure 9a illustrates the resultant PGA distribution map,
729 now ~~encompassing-incorporates~~ site amplifications specifically tailored for the NWYR
730 region. Notably, our findings reveal minimal alterations in the PGA distribution,
731 particularly ~~in proximity~~near to fault lines, where PGA values remain consistent or
732 exceed 0.4 g (as detailed in Table 1).

733 **3.6.2 Landslide Probabilities Derived from Modeled PGA Values**

734

735 Using simulated ground motion data from potential earthquake scenarios, we
736 conducted a thorough assessment of landslide susceptibility in the affected regions. Our
737 analysis employed a machine learning framework, following the methodology outlined
738 by Xu et al. (2019), to develop a predictive model for earthquake-induced landslides.

Formatted: Heading 3, Indent: First line: 0 ch, Line spacing: single

Formatted: Heading 3, Line spacing: single

739 This model was trained utilizing data from nine earthquakes, ranging from the 1999
740 M_w 7.7 Chichi earthquake to the 2017 M_w 6.5 Jiuzhaigou earthquake, all of which
741 occurred within or near China. The training dataset comprised samples of earthquake-
742 induced landslides along ~~with~~side 13 relevant factors. These factors ~~encompassed~~
743 ~~included various~~diverse parameters such as elevation, slope angle, slope aspect, land
744 cover, proximity to faults, geological characteristics, average annual rainfall, and PGA.

745 Leveraging this ~~comprehensive~~rich dataset, we ~~constructed~~developed a robust
746 predictive model capable of ~~discerning~~assessing landslide probabilities.

747 ~~_____~~ (et al., 2020)

748 ~~_____~~

749 ~~We used a logistic regression model, well-regarded for its robust performance in~~
750 ~~machine learning. Unlike previous models (e.g., Nowicki et al., 2014; Wang and Rathje,~~
751 ~~2015; Parker et al., 2017) for calculating~~estimating earthquake-triggered landslide
752 ~~hazards.~~Our model directly assessed the absolute probability of landslide
753 ~~occurrence.~~ This probability is ~~represented as the percentage of the landslide area~~
754 ~~within a given region relative to the total area of the region (Shao et al., 2020).~~

755 ~~This is represented as the percentage of the landslide area within a region relative~~
756 ~~to the region's total area (Shao et al., 2020).~~ As a result, our hazard estimates have a true
757 probabilistic meaning, reflecting the actual probability of landslide occurrence rather
758 ~~than being merely serving as a formal expression of probability.~~

759 ~~We then calculated the probabilistic seismic susceptibility for a specific point in~~
760 ~~time within the study area, which producing~~s a probabilistic seismic peak ground
761 ~~acceleration (PGA)~~ distribution map. By using this probabilistic PGA map as input for
762 our model, we ~~can~~ estimate the corresponding probability of earthquake-triggered
763 ~~landslide occurrence. We employed~~ ~~these~~his steps as ~~forms~~ the basis of our approach

764 [to calculating the probability of such landslides.](#)

765
766
767 Figure_9b illustrates the resultant landslide probability map for the NWYR region.
768 Notably, areas exhibiting with high PGA distribution correspond closely correspond to
769 regions with elevated landslide probabilities. For instance, notable areas include the
770 northern end of the Zhongdian fault, the Jinpingshan fault, the Yulong East fault, the
771 northern end of the Heqing-Eryuan fault, the northern part of the Chenghai fault, and
772 the eastern section of the Lijiang-Xiaojinhe fault (the F2~F4 segments). Of particular
773 significance are regions surrounding the Yulong East fault and the convergence zone of
774 the Lijiang-Xiaojinhe fault and the Zhongdian fault. These areas exhibit pronounced
775 differences in [altitudeelevation](#), ample rainfall, and elevated PGA values, making them
776 particularly susceptible to landslide occurrences.

777
778 By integrating multiple geospatial factors and leveraging advanced machine
779 learning techniques, our analysis provides valuable insights into landslide susceptibility
780 in earthquake-prone regions, aiding in effective risk management and mitigation
781 strategies.

782
783 Figure 9. (a) PGA distribution Map considering different site amplifications; (b) the

784 probabilities of landslide occurrence impacted by the PGA values.

785

786 **4 Discussion and Conclusion**

787 In seismic hazard analysis, understanding fault behaviors, such as slip rates and
788 geometries, is crucial for accurately modeling future seismic activity rates.
789 Concurrently, historical earthquake occurrence rates provide a foundational basis for
790 estimating these future rates. Notably, attention must also be given to earthquakes
791 involving multi-segment ruptures, which may not be fully documented in historical
792 records. In this article, we introduce a new seismic hazard model for NWYR, where the
793 Tibetan Plateau boundary intersects with local low-crustal flow.

794 **4.1 Model Limitations and ~~Corresponding~~Mitigation Measures**

795 Our seismic hazard modeling for NWYR represents our current understanding of
796 average earthquake hazards in the region based on available data. The results are
797 affected by ~~numerous~~various epistemic and aleatory uncertainties inherent in seismic
798 hazard modeling processes, including the MFD, fault geometry, fault type, slip rate, and
799 variability in GMPEs. ~~Mitigating~~Addressing the impact of these uncertainties is
800 crucial~~ital~~ for ~~accurate~~ensuring accurate seismic hazard assessments.

801 The MFD relationship, calculated from historical earthquakes, is essential for
802 determining seismicity rate ratios across different magnitude bins. Variations in the
803 MFD ~~will~~ directly influences the distribution of the modeled seismicity rates. In this
804 study, we chose the G-R relationship over the Y-C relationship due to the regional
805 fragmented tectonic environment. The calculated b -value of 0.96 aligns closely with
806 the expected value of 1 found in seismically active regions (Pacheco et al., 1992).

808 ~~-To derive~~estimate earthquake magnitudes on fault segments, we employed
809 rupture scaling relationships based on historical rupture parameters of earthquakes in
810 China Mainland, as proposed by Cheng et al. (2020), ensuring consistency with unique
811 tectonic characteristics. Achieving more precise MFDs and rupture scaling laws
812 necessitates further refinement in methodology and the use of reliable catalogs specific
813 to the study area. Achieving more accurate MFDs and rupture scaling laws will require
814 further methodological refinement and the use of reliable, region-specific earthquake
815 catalogs.

816 For fault geometry, type, and slip rates, we relied exclusively on recent field
817 investigation data. In compiling fault rupture models for NWYR, we analyzed these
818 geological data under a unified tectonic stress field, ensuring coordinated fault system
819 movements. The variability in GMPEs is complex, influenced by factors such as
820 earthquake rupture characteristics, seismic wave propagation, and site conditions.
821 Consequently, we incorporated Quaternary sediment site amplification effects on PGA
822 values. Addressing basin effects on ground motion requires dynamic simulations to
823 achieve more precise results.

825 4.2.1 Multi-segment Rupturing Hazards in NWYR

Formatted: Heading 2, Line spacing: single

826 The complex fault system results in earthquake occurring almost all the faults with
827 various rupture behaviors in the NWYR, while the catalog of historical and paleo-
828 earthquake data only recorded a small portion of these rupturing events. The NWYR
829 serves as the boundary region between China and Myanmar. This area is predominantly
830 inhabited by ethnic minorities in China, resulting in limited written documentation of
831 its history, particularly regarding earthquake disasters.

832 ~~Nevertheless~~However, some significant earthquakes have been documented,
833 particularly those that ~~have had a seismic-impacted~~ ~~ed~~ ~~on~~-major cities like Dali, e.g., the
834 1515 M7.8 Yongsheng earthquake ~~in Yongsheng~~ ruptured two ~~continuous-linked~~
835 segments of the Chenghai fault (Institute of Geology-State Seismological Bureau and
836 Yunnan Seismological Bureau, 1990). The historical earthquake catalog used in our
837 seismic hazard modeling often ~~struggles-fails~~ to include all ~~possible these combinations~~
838 ~~of ruptured~~ scenarios ~~that occurred in the past~~. ~~To address this, What~~ we have ~~done is~~
839 ~~to search~~explored reasonable models for potential ~~-for possible~~ rupture combinations
840 and calculate their seismicity rates ~~to include in our model.~~

841 These rupture combinations might be constrained by various factors, such as the
842 geometry of fault segments, the width of the step-over between each pair of segments,
843 and the maturity of the fault steps (Cunningham and Mann, 2007; Biasi and Wesnousky,
844 2017). For strike-slip faults, a step-over width of 5 km is often used to assess the
845 ~~reasonableness~~plausibility of the rupture combinations (e.g., Biasi and Wesnousky,
846 2017). However, in the NWYR, where faults are ~~situated with~~~~located in the a~~ conduit
847 of ductile low-crust flow, all step-overs ~~are less than have 5 km wide,ths of less than 5~~
848 ~~km-~~ except for the approximately ~~-the one of ~7 km step-over~~ between the F20 and
849 F21 segments. Hence, we advocate that the intersection relationship between faults is
850 the primary determinant of whether multi-segment rupture events occur among fault
851 segments in this region.

852

853 **4.32 Implication of the small-block rotation in NWYR**

854 The Holocene strike-slip motion of the Lijiang-Xiaojinhe fault ~~behaves-plays at the~~
855 dominant role in this region, ~~and~~ intersecting boths the Heqing-Eryuan fault and the

Formatted: Font: (Default) Times New Roman, 小四

Formatted: Font: (Default) Times New Roman, 小四

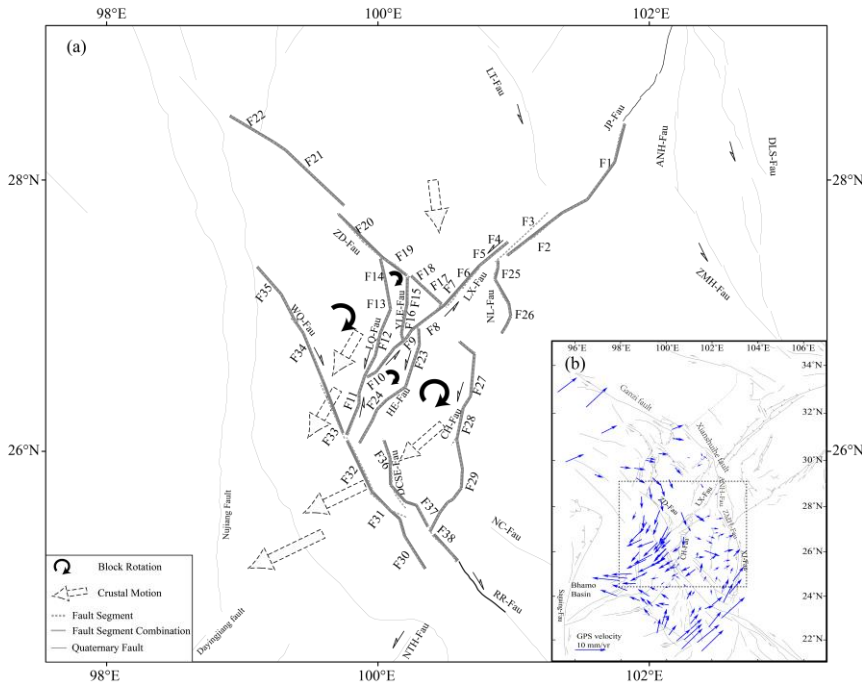

Formatted: Heading 2, Line spacing: single

856 Yulong East fault. Model 1 also confirms ~~ed~~ the capability of the entire rupture of the
857 F4~F10 segments of the Lijiang-Xiaojinhe fault. ~~Additionally, the Lijiang-Xiaojinhe~~
858 ~~fault separates T~~the Chenghai fault ~~from and~~ the Zhongdian fault ~~also are separated by~~
859 ~~the Lijiang-Xiaojianghe fault, challenging which differs~~ the view of Wang et al. (1998)
860 that the Dali fault ~~(including the Longpan-Qiaohou fault and the Chenghai fault)~~ is
861 the primary fault in this region. The Longpan-Qiaohou fault obstructs the westward
862 continuation of the Lijiang-Xiaojinhe fault, and simultaneously, the F11 segment also
863 resists rupturing in conjunction with the Lijiang-Xiaojinhe fault (Model 4 in Figure 4).
864 In contrast, the Weixi-Qiaohou fault (WQ-F) and the Tongdian-Weishan fault (TW-F)
865 ~~belong to are part of~~ distinct small-blocks and therefore cannot rupture simultaneously,
866 as depicted in Figure 10a. This indicates that the northern end of the Red River fault
867 is intercepted by the Longpan-Qiaohou fault. ~~In our model, t~~The Zhongdian fault (ZD-
868 F) ~~is was~~ separated ~~for to~~ rupture ~~in our model~~ (Model 1 in Figure 4), ~~especially~~
869 ~~particularly~~ for the F17~F18 segments combination and the F19~F20 segments
870 combination. ~~Here, w~~We propose that the normal- and strike-slip of the Yulong East
871 fault poses a greater destructive potential to the Zhongdian fault compared to the strike-
872 slip of the Longpan-Qiaohou fault.

873

874 Hence, our ~~configurations of~~ multi-segment rupture ~~configurations~~ portrayed in
875 Model 1 of Figure 4 ~~correspond align with to~~ the rotational patterns noted in the small
876 block delineated in the NWYR by Wang et al. (1998). We illustrate ~~d~~ this clockwise
877 rotation of the small blocks in the NWYR in Figure 10a. This clockwise rotation ~~is was~~
878 further supported by GPS observations to the west of the Xianshuihe fault, the
879 Anninghe fault, and the Xiaojiang fault, after ~~eliminating removal of~~ the entire
880 movement (Figure 10b) (Cheng et al., 2012).

881 In Figure 10b, the area where the Nujiang fault intersects with the Dayingjiang
 882 fault experiences the strongest extensional forces. Rangin et al. (2013) and Lindsey et
 883 al. (2023) proposed that the dynamic source of this extensional tectonic environment
 884 was the side effect of the gravitational collapse of the Tibetan Plateau with the
 885 westwards of upper crust faster than the lower crust (Rangin et al., 2013; Lindsey et al.,
 886 2023). This extensional force ~~significantly affectsexerts obviously on~~ the faults in our
 887 model, ~~driv~~making the rotation of small blocks, and the normal slip of the regional
 888 faults, e.g., the Diancangshan fault and the Chenghai fault.

889
 890 Figure 10 a. Kinematic Model of the faults in the NWYR; b. Regional GPS
 891 motion after removing the whole movement (Cheng et al., 2012).

892

Formatted: Heading 2, Indent: First line: 0 ch, Line spacing: single

893 4.4 Conclusions

894 ~~In conclusion, our study has provided valuable insights into the seismic hazard~~
895 ~~present in the NWYR. By developing fault segmentation models based on recent~~
896 ~~geological research and utilizing advanced simulation techniques, we have enhanced~~
897 ~~our understanding of fault activities and seismicity rates across the region. This study~~
898 ~~presents a comprehensive seismic hazard model for the NWYR, integrating fault slip~~
899 ~~rates and historical seismicity data to ~~evaluate~~assess the risks of multi-segment ruptures~~
900 ~~and landslide occurrences. By leveraging fault slip rates and fault geometrical~~
901 ~~distributions in the NWYR, we employed the ~~iterative~~simulation method within the~~
902 ~~SHERIFS code to ~~simulate~~calculate seismicity rates for both single-segment and multi-~~
903 ~~segment ruptures. This work ~~underscore~~highlights the complexity of the fault systems~~
904 ~~within the region's block rotational tectonic environment. Our study ~~provides~~has~~
905 ~~yielded~~ valuable insights into the seismic hazards present in the NWYR. Through the
906 development of fault segmentation models based on recent geological research and the
907 application of advanced simulation techniques, we have significantly enhanced our
908 understanding of fault activity and seismicity rates across the region. ~~Through careful~~
909 ~~analysis and consideration of fault segmentation, fault slip rates, and historical~~
910 ~~seismicity, w~~~~We~~ ~~also~~have identified multi-segment models that best represent the
911 observed data.

912
913 Our calculations of PGA with a 10% probability of exceedance within 50 years
914 offer ~~crueial~~essential information for assessing seismic risk in the NWYR. The PGA
915 values, associated with obvious latitude difference ~~and~~, abundant precipitation, ~~increase~~
916 ~~the likelihood~~are prone to occurrence of landslides. _

917 Furthermore, our investigation into multi-segment rupture combinations has

918 illuminated potential scenarios for seismic events in the region. ~~By~~~~Through~~~~the~~
919 integration ~~of~~ these findings, we have generated a more comprehensive assessment of
920 seismic hazards and landslide probabilities. These factors are intertwined with the
921 regional small block rotation induced by the low-crustal flow and gravitational collapse
922 along the southeastern frontier of the Tibetan Plateau.

923
924 Future seismic hazard work can be improved by utilizing geophysical data to
925 understand fault structures where strong earthquakes are developing (Xu et al., 2017),
926 applying geodetic data to assess energy accumulation on fault segments (e.g., Yao and
927 Yang, 2023), using microseismicity relocation data to reveal fault asperities (Lay and
928 Nishenko, 2022), and employing dynamic rupture simulations of single and multi-
929 segments to enhance earthquake motion predictions (e.g., Zhang et al., 2017). These
930 studies on fault behaviors, interactions, and multi-segment ruptures are vital for
931 ~~improving~~~~enhancing~~ seismic hazard assessments. Staying vigilant and proactive in
932 seismic risk management will better protect communities and infrastructure in the
933 NWYR and beyond.
